## DISSERTATION

Zur
Erlangung des Doktorgrades der Naturwissenschaften
(Dr. rer. nat.)
dem
Fachbereich Chemie
der Philipps-Universität Marburg
vorgelegt von

## Yu Chen

aus Liaoning/China

Marburg/Lahn 2000

Vom Fachbereich Chemie der Philipps-Universität Marburg als Dissertation angenommen am:
Tag der mündlichen Prüfung: 29.11.2000

Erstgutachter:
Prof. Dr. G. Frenking
Zweitgutachter:
Prof. Dr. W. Petz

## Vorwort

Die vorliegende Arbeit wurde am Fachbereich Chemie der Philipps-Universität Marburg/Lahn unter der Leitung von Herrn Prof. Dr. G. Frenking in der Zeit von Oktober 1996 bis Mai 2000 angefertigt.

Herrn Prof. Dr. G. Frenking danke ich sehr herzlich für die interessante Themenstellung, die geduldige Betreuung, anregende Diskussionen und wertvolle, ideenreiche Ratschläge sowie für hervorragende Arbeitsbedingungen.

Meinen Kollegen des AK Prof. Dr. G. Frenking möchte ich für das sehr gute Arbeitsklima und stete Hilfsbereitschaft danken. Besonderer Dank gebührt Dr. Michael Diedenhofen, dessen Hilfe am Anfang meines Aufenthaltes in Marburg für mich sehr wichtig war, Nicolaus Fröhlich für eine Vielzahl technischer Hilfen und natürlich auch für seine „10 Zwerge". Dr. Michael Hartmann und Dr. Thomas Wagener sind dafür zu danken, sich Mühe gegeben zu haben, die Arbeit zu lesen und zu korrigieren.

Mein Dank gilt allen Mitarbeitern der Hochschulrechenzentren der PhilippsUniversität Marburg, der Technischen Universität Darmstadt, der Justus-LiebigUniversität Gießen, der Universität Frankfurt, der Universität Kassel, und der Universität Stuttgart.

Für die finanzielle Unterstützung bedanke ich mich bei der Deutschen Forschungsgemeinschaft (DFG).

Schließlich danke ich meiner Ehefrau Shuhua Yan und meiner Tochter für ihre liebe Unterstützung.

Die Ergebnisse dieser Arbeit wurden bereits teilweise veröffentlicht:
(1) Chen, Y.; Petz, W.; Frenking, G. Organometallics, 2000, 19, 2698
(2) Chen, Y.; Hartmann, M.; Frenking, G. Eur. J. Inorg. Chem., in press
(3) Chen, Y.; Hartmann, M.; Frenking, G. submitted for publication

## Chapter 1. Introduction

Iron carbonyl compounds continue to be an extensively examined area of organometallic chemistry, because the simple carbonyl compounds are both inexpensive and versatile reagents. ${ }^{1}$ It is well established ${ }^{2}$ that the chemistry of main group organometallics is governed by the group the metal belongs to, whereas for organotransition metal compounds the nature of the ligand dominates. In this work, a thorough investigation of iron complexes with various ligands coordinated to the complex-fragment $\mathrm{Fe}(\mathrm{CO})_{4}$ is presented, in order to enrich the understanding of iron carbonyl complexes in many different aspects.

As a starting point, the geometries, frequencies, and $\mathrm{Fe}-\mathrm{L}$ bond dissociation energies of iron-carbonyl complexes are calculated at a gradient corrected DFT level and improved energies calculations are obtained using the $\operatorname{CCSD}(\mathrm{T})$ of single-point calculations. Based on the fully optimized geometries and other data, several selected topics are carefully discussed in their respective chapter of this thesis.

In trigonal bipyramidal carbonyl complexes containing a $\mathrm{d}^{8}$-metal, two positions of a selected ligand L , namely the axial and equatorial coordinate sites, are in principle possible. This ligand site preference of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ complexes is the first topic discussed in this work. After briefly introducing the computational background, the relative strengths of $\sigma$-donation and $\pi$-backdonation of different ligands that governs the ligand's favor coordination site are discussed, on the basis of NBO analysis and the CDA partitioning scheme.

Besides, the bonding situation of a full series of metal-carbon bonds TM-CR ${ }_{2}$, TM-CR, and TM-C has been examined with the NBO partitioning scheme and the AIM topological analysis of the electron density. This gives us a deeper insight of the bonding situation in TM carbene, carbyne, and carbon complexes, having donoracceptor bonds in contrast to their respective shared-electron isomers.

The following section of this thesis is devoted to the $\mathrm{N}_{2}$-fixation process. Nitrogen fixation has been an attractive and challenging topics in the past decades. The
activation processes of dinitrogen and the stepwise hydrogenation are examined from both structural and energetical viewpoints.
${ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR chemical shifts of fluorine substituted iron tetracarbonyl complexes and related compounds are calculated at the DFT-GIAO level, in order to provide a useful help for the characterization of the $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ complex.

Finally, a short summary was given in Chapter 7.

The complexes presented in this thesis are numbered independently in each chapter. The Cartesian coordinates of all iron complexes and selected free ligand molecules are given in Appendix.

## Chapter 2. The Theoretical Background

The aim of $a b$ initio molecular orbital theory ${ }^{3}$ is to predict the properties of atoms and molecules. It is based on the fundamental laws of quantum mechanics using a variety of mathematical transformations and approximation-techniques to solve the equations that build up this theory. In order to gain the best efficiency/cost ratio at a suitable level of theory and to comment and interpret the results from such calculations, reviewing the historical background is essential.

### 2.1 Molecular Energy

### 2.1.1 The Schrödinger Equation

In quantum mechanics, the state of a system is fully described by the wave function $\Phi(r, t)$, where $r$ are spatial coordinates of the particles that constitute the system and $t$ is the time. The product of $\Phi$ with its complex conjugate is defined as the probability distribution of the particle, i.e. the probability of finding a particle in its volume element $d r$ around its point $r$ at the time $t$. The dynamical evolution of the wave function with time is described by the time-dependent Schrödinger equation ${ }^{4}$

$$
\begin{equation*}
i \hbar \frac{\partial \Phi(r, t)}{\partial t}=\hat{H} \Phi(r, t)=E \Phi(r, t) \tag{2.1}
\end{equation*}
$$

where $\hat{H}$ is the Hamiltonian operator for the system, corresponding to the total energy.

In most cases, time-dependent interaction of atoms and molecules can be neglected. The Schrödinger equation is thus separated into equations for time and space variation of the wave function using the variable separation $\Phi(r, t)=\Phi(r) \Phi(t)$. The time-independent Schrödinger equation is therefore given as:

$$
\begin{equation*}
\hat{H} \Phi(r)=E \Phi(r) \tag{2.2}
\end{equation*}
$$

where

$$
\begin{equation*}
\hat{H}=-\sum_{i=1}^{N} \frac{1}{2} \nabla_{i}^{2}-\sum_{A=1}^{M} \frac{1}{2 M_{A}} \nabla_{A}^{2}-\sum_{i}^{N} \sum_{A}^{M} \frac{Z_{A}}{r_{i A}}+\sum_{i}^{N} \sum_{j>i}^{N} \frac{1}{r_{i j}}+\sum_{A=1}^{M} \sum_{B>A}^{M} \frac{Z_{A} Z_{B}}{R_{A B}} \tag{2.3}
\end{equation*}
$$

Here $i$ and $j$ are indices of electrons whereas $A$ and $B$ are indices of atomic nuclei. $M_{A}$ is the ratio of the mass of nucleus $A$ to an electron, and $Z_{A}$ is the atomic number of nucleus $A$. The distance between the $i$ th and the $j$ th electron is $r_{i j}$; the distance between the $A$ th nucleus and the $B$ th nucleus is $R_{A B} ; r_{i A}$ specifies the distance between electron $i$ and nucleus $A$. The first and second terms in Eq. 2.3 are the kinetic energy operators of the electrons and the nuclei, respectively. The third term is the electronnucleus attraction energy operator, whereas the fourth and fifth terms represent the repulsion energy operator of the electron-electron and the nucleus-nucleus repulsion, respectively.

Note that $\hat{H} \Phi(r)=E \Phi(r)$ is a non-relativistic description of the system which is not valid when the velocities of particles approach the speed of light. The mass of a moving particle $m$ increases with its velocity $v$ according to

$$
\begin{equation*}
m=m_{0}\left[1-(v / c)^{2}\right]^{-1 / 2} \tag{2.4}
\end{equation*}
$$

where $m_{0}$ and $c$ are the rest mass and the speed of light, respectively. Thus, timeindependent Schrödinger equation does not give an accurate description of the core electrons in large nuclei. Relativistic effect must be considered for the heaviest elements of the periodic table, but is neglected throughout this thesis since only Fe-carbonyl complexes are considered.

Because of the large difference between the mass of the electrons and that of the nuclei, the electrons can respond almost instantaneously to a displacement of the nuclei. Therefore it is reasonable to regard the nuclei as fixed and to solve the Schrödinger equation only for the electrons in the static electronic potential arising from these nuclei. This, the so-called Born-Oppenheimer approximation ${ }^{5}$, is very reliable for electronic ground states. The set of solutions obtained in different arrangements of nuclei is used to construct the potential energy surface (PES) of a polyatomic species.

For an isolated N -electron atomic or molecular system within the BornOppenheimer, nonrelativistic approximation, the electronic Schödinger equation is given by

$$
\begin{equation*}
\hat{H}_{\text {elec }} \Phi_{\text {elec }}=E_{\text {elec }} \Phi_{\text {elec }} \tag{2.5}
\end{equation*}
$$

where $E_{\text {elec }}=E_{\text {elec }}\left(\left\{R_{A}\right\}\right)$ is the electronic energy, $\Phi_{\text {elec }}=\Phi_{\text {elec }}\left(\left\{r_{i}\right\} ;\left\{R_{A}\right\}\right)$ is the wave function which describes the motion of the electrons and explicitly depends on the electronic coordinates but depends parametrically on the nuclear coordinates, as does the electronic energy. $\hat{H}_{\text {elec }}$ is the electronic Hamiltonian operator:

$$
\begin{equation*}
\hat{H}_{\text {elec }}=-\sum_{i=1}^{N} \frac{1}{2} \nabla_{i}^{2}-\sum_{i}^{N} \sum_{A}^{M} \frac{Z_{A}}{r_{i A}}+\sum_{i}^{N} \sum_{j>i}^{N} \frac{1}{r_{i j}} \tag{2.6}
\end{equation*}
$$

The total energy $E_{\text {tot }}$ is the electronic energy $E_{\text {elec }}$ including the nucleus repulsion energy according to

$$
\begin{equation*}
E_{\text {tot }}=E_{\text {elec }}+\sum_{A=1}^{M} \sum_{B>A}^{M} \frac{Z_{A} Z_{B}}{R_{A B}} \tag{2.7}
\end{equation*}
$$

### 2.1.2 The Hartree-Fock Approximation ${ }^{6}$

Because electrons are ferminons, $\Phi$ also must be antisymmetric with respect to the interchange of the coordinates (both space and spin) of any two electrons. That is:

$$
\begin{equation*}
\Phi\left(x_{1}, \ldots, x_{i}, \ldots x_{j}, \ldots x_{N}\right)=-\Phi\left(x_{1}, \ldots, x_{j}, \ldots x_{i}, \ldots x_{N}\right) \tag{2.8}
\end{equation*}
$$

This requirement is a general statement of the familiar Pauli exclusion principle ${ }^{7}$ introducing the concept of spin orbitals. A spin orbital $\chi_{i}$ is a product of a spatial orbital wave function $\psi$ and a spin function. For different spins, $\alpha$ and $\beta$ are used to refer $s=1 / 2$ and $-1 / 2$, respectively. Suppose now that $\Psi$ is approximated as an
antisymmetrized product of orthonormal spin orbitals $\chi_{i}$, the Slater ${ }^{8}$ determinant for a system has the following form:

$$
\Psi\left(x_{1}, x_{2}, \ldots, x_{N}\right)=\frac{1}{\sqrt{N!}}\left|\begin{array}{cccc}
\chi_{i}\left(x_{1}\right) & \chi_{j}\left(x_{1}\right) & \ldots & \chi_{k}\left(x_{1}\right)  \tag{2.9}\\
\chi_{i}\left(x_{2}\right) & \chi_{j}\left(x_{2}\right) & \ldots & \chi_{k}\left(x_{2}\right) \\
\cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot \\
\chi_{i}\left(x_{N}\right) & \chi_{j}\left(x_{N}\right) & \ldots & \chi_{k}\left(x_{N}\right)
\end{array}\right|
$$

with the diagonal elements written as:

$$
\begin{equation*}
\Psi\left(x_{1}, x_{2}, \ldots, x_{N}\right)=\left|\chi_{i}\left(x_{1}\right) \chi_{j}\left(x_{2}\right) \ldots \chi_{k}\left(x_{N}\right)\right\rangle \tag{2.10}
\end{equation*}
$$

On the basis of the variation theory, ${ }^{9}$ the lowest value of $E$ is indicated as $E_{0}$ identified as the electronic energy for the selected nuclear configuration.

$$
\begin{equation*}
E_{0}=\frac{\left\langle\Psi_{0}\right| \hat{H}\left|\Psi_{0}\right\rangle}{\left\langle\Psi_{0} \mid \Psi_{0}\right\rangle} \quad \text { where } \quad \Psi_{0}=\left|\chi_{1}, \chi_{2}, \ldots, \chi_{N}\right\rangle \tag{2.11}
\end{equation*}
$$

On the one hand, each spin orbital must be obtained by solving an equation including the Fock operator $\hat{f}$, e.g. for coordinate 1

$$
\begin{equation*}
\hat{f}_{i}(1) \quad \chi_{i}(1)=\varepsilon_{i} \quad \chi_{i}(1) \tag{2.12}
\end{equation*}
$$

where the Fock operator is the sum of the one-electron operator $\hat{h}_{\text {core }}$ and the twoelectron operators $\hat{J}_{j}, \hat{K}_{j}$.

$$
\begin{equation*}
\hat{f}(1)=\hat{h}_{\text {core }}(1)+\sum_{j} 2 \hat{J}_{j}(1)-\hat{K}_{j}(1) \tag{2.12a}
\end{equation*}
$$

On the other hand, however, this operator depends on the spin orbitals of all other $\mathrm{N}-1$ electrons, because $v^{H F}(i)$ is the average potential experienced by the $i$ th electron due to
the presence of the other electrons, which is constituted by the Coulomb operator $\hat{J}_{j}(1)$ and the non-classical exchange operator $\hat{K}_{j}(1)$.

$$
\begin{gather*}
\hat{J}_{j}(1)=\int\left|\chi_{j}(2)\right|^{2} \frac{1}{r_{12}} d x_{2}  \tag{2.12b}\\
\hat{K}_{j}(1)=\int \chi_{j}^{*}(2) P_{12} \chi_{j}(2) \frac{1}{r_{12}} d x_{2} \tag{2.12c}
\end{gather*}
$$

It appears that to set up the HF equations, one must already know the solution beforehand. It is therefore necessary to adopt an iterative process to solve these equations. By using a self-consistent procedure, a trial set of spin orbitals is formulated and used to formulate the Fock operator, then the HF equation are solved to obtain a new set of spin orbitals which are then used to build up a refined Fock operator. These cycles are repeated until the chosen convergence criteria are satisfied.

The HF equations might be solved numerically according to the suggestion of Roothaan and Hall. ${ }^{10}$ A set of known spatial basis functions (for example, atomic orbital basis functions) is introduced and the unknown molecular orbitals are expanded in the linear expansion.

$$
\begin{equation*}
\psi_{i}=\sum_{\mu}^{K} C_{i \mu} \phi_{\mu} \tag{2.13}
\end{equation*}
$$

If the set of $\phi_{\mu}$ is complete, the expansion would be exact. The problem of calculating the HF molecular orbitals is then reduced to the problem of calculating a set of expansion coefficients. Substituting Eq. 2.13 into the HF equation 2.12 therefore gives

$$
\begin{equation*}
\mathbf{F C}=\mathbf{S C} \boldsymbol{\varepsilon} \tag{2.14}
\end{equation*}
$$

where $\mathbf{F}, \mathbf{S}, \mathbf{C}$, and $\boldsymbol{\varepsilon}$ are Fock matrix, overlap matrix, square matrix of the expansion coefficients, and the diagonal matrix of the orbital energies $\varepsilon_{i}$, respectively. An explicit expression for the Fock matrix element is

$$
\begin{equation*}
F_{\mu \nu}=H_{\mu \nu}^{\text {core }}+\sum_{\lambda \sigma} \rho_{\lambda \sigma}\left[(\mu \nu \mid \sigma \lambda)-\frac{1}{2}(\mu \lambda \mid \sigma v)\right] \tag{2.14a}
\end{equation*}
$$

and depends on the elements of the core-Hamiltonian matrix $H$, the density matrix $\rho$, and the two-electron integrals.

In SCF calculations it is common to use restricted HF (RHF) wave functions in which the spatial components of the spin orbitals are identical for each member of a pair of electrons. For open-shell states of atoms and molecule two procedures are used instead. One is the restricted open shell HF (ROHF) approch, in which all the electrons except those that occupy open-shell orbitals are forced to occupy the same spatial orbitals. Another method considers unrestricted open-shell HF (UHF) wavefunction, where the constraint of pairwise occupied orbitals is relaxed. Generally, a lower variational energy is predicted for UHF than for RHF. However, one disadvantage of the UHF approach is that such a function is not an eigenfunction of $S^{2}$.

### 2.1.3 Electron Correlation Methods

The motion of the electrons is correlated since the wave function must be antisymmetric with respect to the interchange of any two electrons. The difference between the exact nonrelativistic energy and the Hartree-Fock energy in a given basis set is called the electron correlation energy. Electron correlation based on electron with opposite spin is sometimes called Coulomb correlation, while electron correlation based on the repulsion of electron having the same spin is called Fermi correlation.

The HF method determines the best one-determinant wave function in a given basis set. It is therefore obvious that in order to improve on HF results, the starting point must be a trial wave function which contain more than one Slater-Determinant.

$$
\begin{equation*}
|\Phi\rangle=c_{0}\left|\Psi_{0}\right\rangle+\sum_{r a} c_{a}^{r}\left|\Psi_{a}^{r}\right\rangle+\sum_{\substack{a<b \\ r<s}} c_{a b}^{r s}\left|\Psi_{a b}^{r s}\right\rangle+\sum_{\substack{a<b c<\\ r<s<t}} c_{a b c}^{r s t}\left|\Psi_{a b c}^{r s t}\right\rangle+\ldots \tag{2.15}
\end{equation*}
$$

By replacing occupied MOs in the HF determinant by unoccupied MOs, a whole series of determinants may be generated. These can be denoted according to how many occupied HF-MOs have been replaced, thus leading to Slater determinants which are singly, doubly, triply, quadruply etc. excited relative to the HF determinant. These determinants are often referred to as Singles (S), Doubles (D), Triples (T), Quadruples (Q) with a maximum excitation of N electrons ( N - multiple).

Limiting the number of determinants to only those which can be generated by exciting the valence electrons is known as the frozen core approximation. The contributions of the correlation from core electrons is a constant factor and drops out when calculating relative energies.

There are three main methods for calculating electron correlation: Configuration Interaction (CI), Many Body Perturbation Theory (MBPT) and Coupled Cluster (CC) Theory. The latter two methods are discussed separately in next two sections.

The trial wave functions for CI approach is written as a linear combination of determinants with the expansion coefficients determined under the requirement that the energy should be a minimum (or at least stationary). The MOs used for building the excited Slater determinants are taken from a HF calculation and are held fixed. Inclusion of all possible determinants yields the full CI wave function. This is the best possible wave function within the limitations of the chosen basis set. However, the number of determinants grows significantly with the size of the basis set, and it makes the full CI method infeasible for all but the very smallest systems.

As a systematic procedure for going beyond the HF approximation, Configuration Interaction (CI) has the important advantage that it is variational (i.e., at each it gives an upper bound to the exact energy), but it has the disadvantage that it is only size consistent when all possible excitations are incorporated into the trial function (i.e., full CI). All forms of truncated CI such as CISD are not size consistent.

### 2.1.3.1 Many-Body Perturbation Theory (MBPT)

A different systematic procedure for evaluating the correlation energy, which is not variational in the sense that it does not in general give energies that are upper bounds to the exact energy but is size consistent at each level, is perturbation theory (PT).

The application of PT to a system composed of many interacting particles is generally called many-body perturbation theory (MBPT). This perturbation method is based on a partitioning of the full Hamiltonian into two pieces,

$$
\begin{equation*}
\hat{H}=\hat{H}_{0}+\lambda \hat{H}^{\prime} \tag{2.16}
\end{equation*}
$$

Because $\hat{H}^{\prime}$ is a small perturbation to $\hat{H}_{0}$, the perturbed wave function and energy can be expressed as a power series in terms of the parameter $\lambda$

$$
\begin{align*}
& \Psi=\Psi_{0}+\lambda \Psi^{(1)}+\lambda^{2} \Psi^{(2)}+\ldots  \tag{2.17}\\
& E=E_{0}+\lambda E^{(1)}+\lambda^{2} E^{(2)}+\ldots
\end{align*}
$$

The perturbed wave functions and energies are substituted back into the Schrödinger equation. After expanding the products, the coefficients on each side of the equation for each power of $\lambda$ can be calculated leading to a series of relations representing successively higher orders of perturbation.

To find the correlation energy for the ground state, the zero-order Hamiltonian from the Fork operators of the HF-SCF method is adopted according to the MøllerPlesset ${ }^{11}$ perturbation theory (MPPT). $\hat{H}_{0}$ is defined as the sum of the one electron Fock operator,

$$
\begin{equation*}
\hat{H}_{0}=\sum_{i} \hat{f}(i) \tag{2.18}
\end{equation*}
$$

$E_{0}$ is the sum of the orbital energies $\varepsilon_{i}$

$$
\begin{equation*}
E_{0}=\sum_{i} \varepsilon_{i} \tag{2.19}
\end{equation*}
$$

A correction of the electron correlation energy is only achieved, if at least a 2 nd order perturbation is considered. The inclusion of such a second-order energy correction is designated as MP2.

For $E^{(2)}$ :

$$
\begin{equation*}
E^{(2)}=\sum_{s} \frac{k \Psi^{(0)}\left|\hat{H}^{\prime}\right| \Psi^{(0)}>\left.\right|^{2}}{E_{0}-E_{s}} \tag{2.20}
\end{equation*}
$$

where

$$
\begin{gather*}
\hat{H}^{\prime}=\hat{H}-\hat{H}_{0}=\sum_{i=1}^{N} \hat{h}(i)+\sum_{i=1}^{N} \sum_{j>i}^{N} r_{i j}^{-1}-\sum_{i=1}^{N} \hat{f}(i) \\
=\sum_{i=1}^{N} \sum_{j>i}^{N} r_{i j}^{-1}-\sum_{i=1}^{N} v^{H F}(i) \tag{2.21}
\end{gather*}
$$

The last term is just the sum of the HF coulomb and exchange potentials. Because $E_{0}$ is the lowest energy eigenvalue of the unperturbed system the value of $E^{(2)}$ will always be negative. The explicit formula for MP2 is

$$
\begin{equation*}
E^{(2)}=\sum_{i<j}^{o c c} \sum_{a<b}^{v i r t} \frac{\left[<\chi_{i} \chi_{j}\left|\chi_{a} \chi_{b}>-<\chi_{i} \chi_{j}\right| \chi_{b} \chi_{a}>\right]^{2}}{\varepsilon_{i}+\varepsilon_{j}-\varepsilon_{a}-\varepsilon_{b}} \tag{2.22}
\end{equation*}
$$

The low cost compared to CI methods makes MP2 calculations to one of the most economical methods for including electron correlation. If MPPT is extended to include third- and fourth-order energy correction, the procedures are referred to as MP3 and MP4, and the algebra involved becomes more and more complicated.

### 2.1.3.2 Density Functional Theory (DFT)

Density function theory has its roots in the work of Thomas and Fermi in the 1920s. ${ }^{12}$ It became a complete and accurate theory only due to the publications in the early 1960s of Hohenberg, Kohn, and Sham. ${ }^{13,14}$ This theory allows one to replace the complicated N -electron wave function $\Psi$ and the associated Schrödinger equation by much simpler electron density $\rho(r)$ and its associated calculational schemes. This is the reason that DFT has been growing in popularity over the past decade. Unfortunately, the form of the functional dependence of the energy on the density $E[\rho(r)]$ is not given by the Hohenberg-Kohn theorem ${ }^{13}$, it is confirmed that such a functional exists.

Following the work of Kohn and Sham, ${ }^{14}$ the approximate functionals employed by current DFT methods partition the electronic energy into several terms:

$$
\begin{equation*}
E=E_{T}+E_{V}+E_{J}+E_{X C} \tag{2.23}
\end{equation*}
$$

where $E_{T}$ is the kinetic energy term arising from the motion of the electrons. $E_{V}$ includes terms describing the potential energy of the nuclear-electron attraction and of the repulsion between pairs of nuclei. $E_{J}$ is the electron-electron repulsion term, also described as the coulomb self-interaction of the electron density, and $E_{X C}$ is the exchange-correlation term and includes the remaining part of the electron-electron interactions, that is (1) the exchange energy arising from the antisymmetry of the quantum mechanical wave function, and (2) the dynamic correction of the motions of individual electrons. Note that all terms except the nuclear-nuclear repulsion are functionals of the electron density $\rho$.
$E_{X C}$ is further divided into exchange and correlation functionals, corresponding to "same-spin" and "mixed-spin" interactions, respectively:

$$
\begin{equation*}
E_{X C}(\rho)=E_{X}(\rho)+E_{C}(\rho) \tag{2.24}
\end{equation*}
$$

Both components on the right side of the equation can be of two distinct types: local functionals depend only on the electron density $\rho$, while gradient-corrected functionals depend on both $\rho$ and its gradient, $\nabla \rho$.

The local exchange functionals (e.g. LDA) were developed to deduce the exchange energy of a uniform electron gas and thus has its shortcoming in describing molecular system. In 1988 Becke $^{15}$ therefore formulated the gradient-corrected exchange functional based on the LDA exchange functional. It succeeds in remedying many of the LDA functional's deficiencies. Similarly, local (e.g. Vosko, Wilk, and Nusair ${ }^{16}$ ) and gradient-corrected (Perdew ${ }^{17}$ ) correlation functionals exist and are widely used. Pure DFT methods are defined by pairing an exchange functional with a correlation functional. For example, BP86 ${ }^{15,17}$, BLYP ${ }^{15,18}$.

In practice, self-consistent Kohn-Sham DFT calculations are performed in an iterative manner analogous to the SCF procedure described for HF. The density may be approximately written in terms of a set of auxiliary one-electron functions, so-called Kohn-Sham orbitals, as

$$
\begin{equation*}
\rho(r)=\sum_{i}^{N}\left|\psi_{i}\right|^{2} \tag{2.25}
\end{equation*}
$$

The Kohn-Sham equations have the form

$$
\begin{equation*}
\hat{h}_{K S} \psi_{i}=\varepsilon_{i} \psi_{i} \tag{2.26}
\end{equation*}
$$

where the operator

$$
\begin{equation*}
\hat{h}_{K S}=-\frac{1}{2} \nabla_{1}^{2}-\sum_{A} \frac{Z_{A}}{r_{1 A}}+\int \frac{\rho(2)}{r_{12}} d r_{2}+v_{X C}(1) \tag{2.27}
\end{equation*}
$$

is similar to the Fock operator in the HF-approach. The corresponding potential $v_{X C}(1)$ is given by a derivative of the energy $E_{X C}$ with respect to the density $\rho$

$$
\begin{equation*}
v_{X C}(1)=\frac{\partial E_{X C}[\rho]}{\partial \rho(r)} \tag{2.28}
\end{equation*}
$$

HF theory also includes an exchange term as part of its formulation. According to the Gaussian user's reference, a Becke ${ }^{19}$-style three-parameter functional (B3LYP) may be defined via the following expression:

$$
\begin{equation*}
E_{X C}^{B 3 L Y P}=E_{X}^{L D A}+c_{0}\left(E_{X}^{H F}-E_{X}^{L D A}\right)+c_{X} E_{X}^{B 88}+E_{C}^{V W N 3}+c_{C}\left(E_{C}^{L Y P}-E_{C}^{V W N 3}\right) \tag{2.29}
\end{equation*}
$$

Here the parameter $c_{0}$ allows any mixture of HF and LDA local exchange. In addition, Becke's gradient correction to the LDA exchange is also included, scaled by the parameter $c_{X}$. Similarly, the VWN3 local correction functional is used, and it may be optionally corrected by the LYP correlation correction via the parameter $c_{C}$. In the formulation of the B3LYP functional, the parameters were determined by fitting them to the atomization energies in the G1 molecule set, the values are: $c_{0}=0.20, c_{X}=0.72$ and $c_{C}=0.81$. Note, however, that LDA densities and PerdewWang $91^{20}$ correlation functional rather than $\mathrm{VWN} 3{ }^{16}$ and $\mathrm{LYP}{ }^{18}$ are used in original paper ${ }^{19}$.
$E_{X C}$ can not be evaluated analytically for DFT methods, so it is computed via numerical integration. Thus, in order to perform the numerical integration a grid of points in space must be employed. A crucial point in comparing different DFT-result based on the same functional is the quality of the chosen integration grid. But for the whole system in this thesis, the quality of grids does not play an important role.

### 2.1.3.3 Coupled Cluster(CC) Theory

Perturbation methods add all types of excitations ( $\mathrm{S}, \mathrm{D}, \mathrm{T}, \mathrm{Q}$ etc.) to the reference wave function to a given order (2, 3, 4 etc.). The idea in Coupled Cluster $(\mathrm{CC})^{21}$ methods is to include all corrections of a given type to infinite order. The coupled cluster wave function is written as

$$
\begin{gather*}
\Psi_{C C}=e^{\hat{T}} \Psi_{0}  \tag{2.30}\\
e^{\hat{T}}=1+\hat{T}+\frac{1}{2} \hat{T^{2}}+\frac{1}{6} \hat{T^{3}}+\ldots=\sum_{k=0}^{\infty} \frac{1}{k!} \hat{T^{k}} \tag{2.31}
\end{gather*}
$$

where the cluster operator $T$ is given by

$$
\begin{equation*}
\hat{T}=\hat{T_{1}}+\hat{T_{2}}+\hat{T_{3}}+\ldots+\hat{T_{N}} \tag{2.32}
\end{equation*}
$$

The $\hat{T}_{i}$ operator acting on a HF reference wave function generates all $i$ th excited Slater determinants.

$$
\begin{align*}
& \hat{T}_{1} \Psi_{0}=\sum_{i}^{o c c} \sum_{a}^{v i r} t_{i}^{a} \Psi_{i}^{a}  \tag{2.33a}\\
& \hat{T}_{2} \Psi_{0}=\sum_{i<j}^{o c c} \sum_{a<b}^{v i r} t_{i j}^{a b} \Psi_{i j}^{a b} \tag{2.33b}
\end{align*}
$$

The expansion coefficients $t$ is called amplitudes.

From Eqs. (2.31) and (2.32) the exponential operator may be written as

$$
\begin{equation*}
e^{\hat{T}}=1+\hat{T_{1}}+\left(\hat{T_{2}}+\frac{1}{2} \hat{T_{1}^{2}}\right)+\left(\hat{T_{3}}+\hat{T_{2}} \hat{T}_{1}+\frac{1}{6} \hat{T_{1}^{3}}\right)+\ldots \tag{2.34}
\end{equation*}
$$

The first term generates the reference HF and the second all singly excited states. The first term in parenthesis generates all doubly excited states. The second parenthesis generates all triply excited states.

Truncated coupled cluster methods are used due to the limitations of computational resources. Including only the $\hat{T}_{1}$ operator does not yield any improvement over HF, as matrix element between the HF and singly excited states are zero. The lowest level of approximation is therefore $\hat{T}=\hat{T}_{2}$, referred to as CCD. Using $\hat{T}=\hat{T}_{1}+\hat{T}_{2}$ gives the CCSD model. The triples contribution may be evaluated by perturbation theory and added to the CCSD results thus resulting in a method abbreviated as $\operatorname{CCSD}(T)$.

If all cluster operators up to $\hat{T_{N}}$ are included in $\hat{T}$, all possible excited determinants are generated and the coupled cluster wave function is equivalent to full CI.

### 2.2 Basis set and Effective Core Potentials (ECPs)

Historically, quantum chemical calculations for atoms and molecules were performed as linear combination of atomic orbitals-molecular orbitals (LCAO-MO).

$$
\begin{equation*}
\psi_{i}=\sum_{\mu}^{n} c_{i \mu} \varphi_{i \mu} \tag{2.35}
\end{equation*}
$$

where $\psi_{i}$ is the $i$-th molecular orbital, $c_{i \mu}$ are the coefficients of linear combination, $\varphi_{i \mu}$ is the $u$-th atomic orbital, and $n$ is the number of atomic orbitals.

Atomic orbitals (AO) are solutions of the HF equations for the atoms. This term may also be replaced by "basis functions". An example for such function are Slater Type Orbitals (STO's) ${ }^{22}$, that were used due to their similarity to the atomic orbitals of the hydrogen atom. They are described by a function depending on spherical coordinates:

$$
\begin{equation*}
\varphi(\zeta, n, l, m ; r, \theta, \phi)=N r^{n-1} e^{-\zeta r} Y_{l m}(\theta, \phi) \tag{2.36}
\end{equation*}
$$

where $N$ is a normalization constant, $\zeta$ is called "exponent", $r, \theta$ and $\phi$ are spherical coordinates, $Y_{l m}$ is the angular momentum and $n, l$ and $m$ are the principal-, angular momentum-, and magnetic quantum numbers, respectively.

Unfortunately, functions of this kind are not suitable for a convenient and fast evaluation of the two-electron integrals. That is why the Gaussian type orbitals (GTO's) ${ }^{23}$ were introduced. One can approximate the shape of the STO function by summing up a number of GTOs with different exponents and coefficients. The GTO is expressed as:

$$
\begin{equation*}
g(\alpha, n, l, m ; x, y, z)=N x^{l} y^{m} z^{n} e^{-\alpha r^{2}} \tag{2.37}
\end{equation*}
$$

where $N$ is a normalization constant, $\alpha$ is the "exponent", $x, y$ and $z$ are cartesian coordinates and $l, m$ and $n$ are simply integral exponents in cartesian coordinates,
which are completely different from the same notations used in STO's due to $r^{2}=x^{2}+y^{2}+z^{2}$.

For quantum chemical calculations, a linear combination of gaussian primitives is usually used as basis functions. Such functions will have their coefficients and exponents fixed. The contractions are sometimes called Contracted Gaussian Type Orbitals (CGTO). Obviously, the best results could be obtained if all coefficients in such gaussian expansions were allowed to vary during molecular calculations. However, the CPU time requirements are more acute.

The first gaussian contractions were obtained by a least square fit to Slater-type atomic orbitals. In the minimal basis set (i.e. SZ; the numbers of zeta $\zeta$ is $\mathrm{N}_{\zeta}=1$ ) only one basis function (contraction) per Slater-type atomic orbital is used. DZ sets $\left(\mathrm{N}_{\zeta}=2\right)$ have two basis functions per orbital, etc. Since valence orbitals of atoms are more affected by forming a bond than the inner (core) orbitals, more basis functions were assigned to describe valence orbitals. This prompted the development of split-valence (SV) basis sets, i.e., basis sets in which more contractions are used to describe valence orbitals than core orbitals. Frequently, the core orbitals are extensive contractions consisting of many primitive gaussians to represent the "cusp" of s-type functions at the position of the nucleus reasonably well. The "zeta" terminology is often augmented with a number of polarization (P) functions. Thus, DZP means double-zeta plus polarization, TZP stands for triple-zeta plus polarization, etc. Occasionally the number of polarization functions is given explicitly, e.g. TZDP, TZ2P, TZ+2P stands for triplezeta plus double polarization. The letter "V" denotes split valence basis sets, e.g., DZV represents basis set with only one contraction for inner orbitals, and two contractions for valence orbitals.

The notation adopted by Pople and co-workers emphasizes also on the nature of split valence basis sets (SV), resulting in the general notation-scheme $\mathrm{n}-\mathrm{ijG}$ or $\mathrm{n}-\mathrm{ijkG}$, which can be decoded as: n-number of primitives for the inner shells, ij or ijk -numbers of primitives for contractions in the valence shell. Pople's basis sets can also be augmented with d-type polarization functions on heavy atoms only ( $\mathrm{n}-\mathrm{ijG}(\mathrm{d}$ ) or n $\mathrm{ijkG}(\mathrm{d})$ ) or on all atoms, with additional p -functions on hydrogen ( $\mathrm{n}-\mathrm{ijG}(\mathrm{d}, \mathrm{p}$ ) or n $\mathrm{ijkG}(\mathrm{d}, \mathrm{p}))$. The polarization functions are important for reproducing chemical bonds.

Basis sets are also frequently augmented with diffuse functions. Such Gaussian function have very small exponents and decay slowly with the distance from the nucleus. Diffuse functions are necessary for a correct description of anions and weak bonds (e.g. hydrogen bonds) and are frequently used for calculations of various properties (e.g. dipole moments, polarizabilities, etc.). The notation is widely used: $\mathrm{n}-\mathrm{ij}+\mathrm{G}$, or $\mathrm{n}-\mathrm{ijk}+\mathrm{G}$ when 1 diffuse s-type or p-type function is added to a standard basis set on heavy atoms. In this case the s- and p-type function have the same exponents.

It was well known for a long time that core (inner) orbitals are in most cases not affected significantly by changes of chemical bonds. This prompted the development of Effective Core Potential (ECP) approaches, which treat inner shell electrons as if they were some averaged potential rather than actual particles. ECP's are not orbitals but modifications to a Hamiltonian, and as such are very efficient computationally. In addition, it is very easy to incorporate relativistic effects into ECPs, whereas all-electron relativistic computations are very expensive. The relativistic effects are very important in describing heavier atoms, and ECP's simplify calculations and at the same time make them more accurate with popular non-relativistic ab initio packages. The core potentials are usually specified for shells that are filled, while basis functions are provided for the rest of electrons (i.e. valence electrons).

The core electrons are replaced by a linear combination of Gaussian functions, called potential functions, which are parameterized using data from all-electron atom calculations as a reference. The Phillips-Kleinman ${ }^{24}$ operator is a starting point for the valence-only approximation. The atomic orbitals are partitioned into valence orbitals $\varphi_{V}$ and core orbital $\varphi_{C}$, which are eigenfunctions of the respective Fock-operator:

$$
\begin{equation*}
\hat{f} \varphi_{V}=\varepsilon_{V} \varphi_{V} \quad \text { and } \quad \hat{f} \varphi_{C}=\varepsilon_{C} \varphi_{C} \tag{2.38}
\end{equation*}
$$

The pseudo-orbital for valence electrons is then

$$
\begin{equation*}
\chi_{V}=\varphi_{V}+\sum_{C} b_{V C} \varphi_{C} \tag{2.39}
\end{equation*}
$$

The nodeless pseudo-orbital is orthogonal to the core orbitals. And the equation for pseudo-orbital is

$$
\begin{array}{r}
\left(\hat{f}+\sum_{C}\left(\varepsilon_{V}-\varepsilon_{C}\right)\left|\varphi_{C}><\varphi_{C}\right|\right) \chi_{V}=\varepsilon_{V} \chi_{V} \text { or } \\
\left(\hat{f}+v^{P K}\right) \chi_{V}=\left(\hat{f^{V}}+v^{P P}\right) \chi_{V}=\varepsilon_{V} \chi_{V} \tag{2.40}
\end{array}
$$

where the Phillips-Kleinman-potential $v^{P P}$ has the form of

$$
\begin{equation*}
v^{P P}=-\frac{Z-N_{V}}{r}+\sum_{k}^{N_{c} / 2}\left(2 \hat{J_{k}^{C}}-\hat{K_{k}^{C}}\right)+\sum_{k}^{N_{c} / 2}\left(\varepsilon_{j}^{V}-\varepsilon_{k}^{c}\right)\left|\chi_{k}><\chi_{k}\right| \tag{2.41}
\end{equation*}
$$

or

$$
\begin{equation*}
v^{P P}=\sum_{l=0}^{l_{\text {max }}} \sum_{m=-l}^{l} \sum_{k} A_{l k} r^{n k} e^{-B_{l k} r^{2}}\left|Y_{l m}><Y_{l m}\right| \tag{2.42}
\end{equation*}
$$

The finally produced ECP are usually tabulated in the literature as parameters of the following expansion:

$$
\begin{equation*}
E C P(r)=\sum_{i=1}^{M} d_{i} r^{n_{i}} e^{-\zeta_{i} r^{2}} \tag{2.43}
\end{equation*}
$$

It is necessary to specify the number of core electrons that are substituted by ECPs for a given atomic center, the largest angular momentum quantum number included in the potential, and number of terms M in the polynomial expansion shown above. For each term in this expansion one need to specify: coefficient $d_{i}$, power $n_{i}$ of the distance from nucleus $r$ and exponent $\zeta_{i}$ of the gaussian function. Since only functions for valence electrons are required the number of necessary basis functions is reduced drastically. Thus, in many cases it would simply be impossible to perform calculations on systems involving heavier elements without ECP's.

The core size and the number of basis functions of the valence orbitals play the most important role among the various parameters needed for calculations of geometries and bond energies. For transition metal complexes, the small core ECP was recommended.

Although ECPs do not have the correct nodal structure for the valence orbitals, it benefits from the reduction of the size of the basis set. The most important point is that
there is no significant difference in accuracy between the ECP and the model potential if basis sets of the same quality are used. The latter potential is proposed and developed by Huzinaga and co-workers ${ }^{25}$.

To get the parameters for the pseudopotentials and the pseudo-orbitals, several methods are used by different groups. In the group of Stoll and Preuss ${ }^{26}$, the difference in atomic excitation energies between the calculated values with ECP and all-electron results was minimized to get optimized parameters, while the principle of shape consistency is adopted from Hay and Wadt ${ }^{27}$.

### 2.3 Geometry Optimization and Characterization of Stationary Point

Geometry optimizations usually attempt to locate minima on the potential energy surface, therefore predicting equilibrium structures of molecular systems. For minima as well as for saddle points, the first derivative of the energy (i.e. the gradient) is zero.

For $N$ atoms, the energy is a function of $3 N-6$ (or $3 N-5$ ) degrees of freedom. The energy $E$ of a molecular system obtained on the basis of the BornOppenheimer approximation is a parametric function of the nuclear coordinates denoted as $X^{+}=\left(X_{1}, X_{2}, \ldots, X_{3 N}\right)$. Moving from $E(X)$ to $E\left(X_{1}\right)$, where $q=\left(X_{1}-X\right)$, the energy may be expanded in a Taylor series about $X$ as follows:

$$
\begin{equation*}
E\left(X_{1}\right)=E(X)+q^{+} f(X)+\frac{1}{2} q^{+} H(X) q^{+}+\ldots \tag{2.44}
\end{equation*}
$$

where the gradient is $f_{i}=\partial E(X) / \partial X_{i}$ and the Hessian is $H_{i j}=\partial^{2} E(X) / \partial X_{i} \partial X_{j}$

Energy calculations and geometry optimizations ignore the vibrations in molecular systems. In reality, however, the nuclei in molecules are constantly in motion. In equilibrium states these vibrations are regular and predictable since molecular frequencies depend on the second derivative of the energy with respect to the nuclear positions, and molecules can be identified by their characteristic spectra.

The zero-point vibration and thermal energy corrections to the total energies can be obtained through harmonic frequency calculations.

Another purpose of the frequency calculations is to identify the nature of stationary point on the potential energy surface found by a geometry optimization. A structure which has $n$ imaginary frequencies is an $n$th order saddle point. Ordinary transition structures are usually characterized by one imaginary frequency since they are first-order saddle points. Whenever a structure yield an imaginary frequency, it means that there is some geometric distortion for which the energy of the system is lower than it is at the current structure. In order to fully understand the nature of a saddle point, one must determine the nature of this deformation by looking at the normal mode corresponding to the imaginary frequency. A further steps towards characterizing a transition state fully is by running intrinsic reaction coordinate (IRC) calculations. Only on the basis of such calculation it can be shown that the transition state connects reactants and products.

### 2.4. Methods for Electronic Structure Analysis

### 2.4.1 Topologic Analysis of Electron Density

The purpose of the "atoms in molecules" (AIM) concept developed by Bader ${ }^{28}$ is to relate molecular properties to those of its constituent atoms by means of a topological analysis of its electron density.

According to Bader's theory, the quantum subsystems (atoms or atomic groups) are open systems defined in real space, their boundaries being determined by a particular property of the electronic charge density.

$$
\begin{align*}
& \rho(1)=N \int \psi^{*}(1,2, \ldots, N) \psi(1,2, \ldots, N) d r_{2} d r_{3} \ldots d r_{N} \\
& =N \int|\psi(1,2, \ldots, N)|^{2} d \tau^{\prime} \tag{2.45}
\end{align*}
$$

where $d \tau^{\prime}$ denotes the spin coordinates of all the electrons and the cartesian coordinates of all electrons but one. The charge density, $\rho$, has a definite value at each point of
space. It is a scalar field defined over three dimensional space. Each topological feature of $\rho$ is associated with a point in space called a critical point $r_{C}$ where the first derivatives $\nabla \rho\left(r_{c}\right)$ of $\rho$ vanish, i.e. $\nabla \rho\left(r_{C}\right)=0$. The second derivative $\nabla^{2} \rho\left(r_{c}\right)$ of the charge density function at this point determines whether it is a maximum, a minimum or a saddle point. It is also called the Laplacian of charge density, which is invariant to the choice of coordinates axes.

The critical point is labeled using the set of values ( $\omega, \mathrm{r}$ ), where $\omega$ is equal to the number of non-zero curvatures of $\rho$ at the critical point and r is the algebraic sum of the sign of the values. The critical points of charge distributions for molecules at or in the neighborhood of energetically stable nuclear configurations are all of rank three ( $\omega$ $=3$ ) while a critical point with $\omega<3$ is degenerate or unstable. For rank three there are four possible signature values (see Table 2.1).

Table 2.1 Four possible critical points of rank three

| $(\omega, \mathrm{r})$ | Properties of the critical point |
| :---: | :---: |
| $(3,-3)$ | Nucleus region |
| $(3,-1)$ | Bond critical point |
| $(3,+1)$ | Ring critical point |
| $(3,+3)$ | Cage critical point |

The properties of the electron density at a bond critical point $(3,-1)$ characterize the interaction defined by its associated trajectories. When $\nabla^{2} \rho\left(r_{C}\right)<0$ and is large in magnitude, $\rho\left(r_{C}\right)$ is also large, and electronic charge is concentrated in the nuclear region, the result is a sharing of electronic charge by both nuclei, as it is found for interactions usually characterized as covalent or polar (shared interactions). For closedshell interactions, as found in ionic, hydrogen-bonded, van der Waals and repulsive interactions, $\rho\left(r_{C}\right)$ is relatively low in value and the value of $\nabla^{2} \rho\left(r_{C}\right)$ is positive. A another quantity used to determine the nature of the interaction is the energy density at the critical point $H_{b}$. It is found that $H_{b}$ has to be negative for all interactions which result from the accumulation of electron density at the bond critical point. The charge density of an interatomic surface attains its maximum value at the bond critical point
and the two associated curvatures of $\rho$ at $r_{C}$ denoted by $\lambda_{1}$ and $\lambda_{2}$ are negative. In a bond with cylindrical symmetry $\lambda_{1}=\lambda_{2}$. If two curvatures are not of equal magnitude, $\lambda_{2}$ may be referred to as the value of the curvature of smallest magnitude. The quantity $\varepsilon=\left[\lambda_{1} / \lambda_{2}-1\right]$ is then called the ellipticity of the bond, which provides a measure of the content to which charge is preferentially accumulated in a given plane.

The qualitative associations of topological features of the electron density with elements of the molecular structure can be viewed by using its associated gradient vector field, which is represented through a display of the trajectories traced out by the $\nabla \rho(r, X)$ for a given molecular geometry. All trajectories terminate at core critical points $(3,-3)$, which behave as a point attractor. The basin of the attractor is defined as the region of space traversed by all trajectories that terminate at the attractor. The "atomic surface" of atom A is the boundary of its basin. The "zero-flux" surface condition is the boundary condition: $\nabla \rho(r) \bullet n(r)=0$ for every point on the interatomic surface $S(r)$ where $n(r)$ is the unit vector normal to the surface at $r$.

### 2.4.2 Natural Bond Orbital (NBO) Analysis

The natural bond orbital (NBO) analysis developed by Weinhold et al. ${ }^{29,30}$ consists of a sequence of transformations from the input basis set such as atomic orbitals (AOs), to various localized basis sets: natural atomic orbitals (NAOs), natural hybrid orbitals (NHOs), natural bond orbitals (NBOs), and natural localized molecular orbitals (NLMOs). The localized sets may be subsequently transformed to delocalized natural orbitals (NOs) or canonical molecular orbitals (MOs).

$$
\mathrm{AOs} \rightarrow \mathrm{NAOs} \rightarrow \mathrm{NHOs} \rightarrow \mathrm{NBOs} \rightarrow \mathrm{NLMOs} \rightarrow \mathrm{NOs} \text { or MOs }
$$

The initial transformation from the one-center basis AOs to NAO is generally nonunitary since basis-AOs are generally nonorthogonal. The subsequent transformations are, however, unitary. Each set of one-center (NAO, NHO) and two-center (NBO, or NLMO) orbitals constitute a complete, orthonormal "chemist's basis set" which is in close correspondence to the picture of localized bonds and lone pairs as basis units of the molecular structure.

1. NOs Conventional natural orbitals are introduced originally by Löwdin ${ }^{31}$, which were derived from properties of the one-particle density operator $\hat{\Gamma}$

$$
\begin{equation*}
\hat{\Gamma}=N \int \psi(1,2, \ldots, N) \psi^{*}\left(1^{\prime}, 2, \ldots, N\right) d \tau_{2} \ldots d \tau_{N} \tag{2.46}
\end{equation*}
$$

and its associated matrix representation $\Gamma$ in an AO basis $\left\{\chi_{i}\right\}$

$$
\begin{equation*}
(\Gamma)_{i j}=\int \chi_{i} *(1) \hat{\Gamma} \chi_{j}\left(1^{\prime}\right) d \tau_{1} d \tau_{1}^{\prime} \tag{2.47}
\end{equation*}
$$

The eigenorbitals of $\hat{\Gamma}$ are $\left\{\phi_{i}{ }^{N O}\right\}$,

$$
\begin{equation*}
\hat{\Gamma} \phi_{i}^{N o}=v_{i} \phi_{i}^{N o} \tag{2.48}
\end{equation*}
$$

which are hence "natural" to the $N$-electron wave function $\psi$ itself. The corresponding eigenvalues are occupation numbers $v_{i}$. The orbitals transform as irreducible representations of the full symmetry point group of the molecule and are therefore completely delocalized.
2. AO $\rightarrow$ NAO's The first step for the construction of NAOs is the diagonalization of the one-center angular symmetry blocks $\Gamma^{(A l m)}$ of the density matrix. This leads to a set of "pre-NAOs", an orthonormal set of orbitals for each atom which are optimal for the atom in its molecular binding environment. On the basis of occupancy these pre-NAOs can be divided into two sets: (1) the "minimal" set $\left\{\phi_{i m}\right\}$, corresponding to all atomic ( $n, l$ ) subshells of non-zero occupation in the atomic ground state electronic configuration, and (2) the "Rydberg" set $\left\{\phi_{i r}\right\}$ consisting the remaining (formal unoccupied) orbitals. The pre-NAOs of one-center overlap those of other centers so that the occupancies of these orbitals can not be used directly to assess the atomic charge.

In the second step, the interatomic overlap is removed. By using the occupancyweighted symmetric orthogonalization (OWSO) procedure, higher weight is given to
preserving the forms of strongly occupied orbitals than of those that play little or no role in describing the atomic electron density. The OWSO procedure is performed on all the minimal functions $\left\{\phi_{i m}\right\}$. For the Rydberg sets $\left\{\phi_{i r}\right\}$, the Schmidt transformation is carried out before OWSO.

$$
\begin{gather*}
\left\{\phi_{i m}\right\}=W_{\text {OWSO }}\left\{\tilde{\phi}_{\text {im }}\right\}  \tag{2.49a}\\
\left\{\tilde{\phi}_{i r}{ }^{s}\right\}=S_{\text {Schmidt }}\left\{\tilde{\phi}_{i r}\right\}  \tag{2.49b}\\
\left\{\phi_{i r}\right\}=W_{\text {OWSO }}\left\{\tilde{\phi}_{i r}{ }^{s}\right\} \tag{2.49c}
\end{gather*}
$$

The final NAOs may also be divided into two sets. The NAOs $\left\{\phi_{i, N M B}\right\}$ of the minimal set are the "natural minimal basis"(NMB), whereas those $\left\{\phi_{i, N R B}\right\}$ of the Rydberg set will be referred as "natural Rydbegr basis"(NRB).

The OWSO procedure is done as follows: Non-orthogonal AOs $\left\{\tilde{\phi}_{i}\right\}$ are transformed to corresponding orthonormal AOs $\left\{\phi_{i}\right\}$ according to:

$$
\begin{gather*}
W_{\text {OWSO }}\left\{\tilde{\phi}_{i}\right\}=\left\{\phi_{i}\right\}  \tag{2.50a}\\
\left\langle\phi_{i} \mid \phi_{j}\right\rangle=\delta_{i j} \tag{2.50b}
\end{gather*}
$$

The transformation matrix $W_{\text {owso }}$ has the property of minimizing the occupancyweighted, mean-squared deviations of the $\phi_{i}$ from the parent non-orthogonal $\tilde{\phi}_{i}$

$$
\begin{equation*}
\min \left\{\sum_{i} w_{i} \int\left|\phi_{i}-\tilde{\phi}_{i}\right|^{2} d \tau\right\} \tag{2.51}
\end{equation*}
$$

where the weighting factor $w_{i}$ is the expectation value of the density operator $\hat{\Gamma}$.

$$
\begin{equation*}
w_{i}=\left\langle\tilde{\phi}_{i}\right| \hat{\Gamma}\left|\tilde{\phi}_{i}\right\rangle \tag{2.52}
\end{equation*}
$$

3. Natural population analysis (NPA) The natural population $q_{i}{ }^{(A)}$ of orbital $\phi_{i}^{(A)}$ on atom A is the diagonal density matrix element in the NAO basis

$$
\begin{equation*}
q_{i}^{(A)}=\left\langle\phi_{i}^{(A)}\right| \hat{\Gamma}\left|\phi_{i}^{(A)}\right\rangle \tag{2.53}
\end{equation*}
$$

which may be summed to give the total number of electrons

$$
\begin{equation*}
q^{(A)}=\sum_{i} q_{i}^{(A)} \tag{2.54}
\end{equation*}
$$

and the natural charge $Q^{(A)}$ on atom A with atomic number $Z^{(A)}$

$$
\begin{equation*}
Q^{(A)}=Z^{(A)}-q^{(A)} \tag{2.55}
\end{equation*}
$$

The populations automatically satisfy the Pauli principle $\left(0 \leq q_{i}^{(A)} \leq 2\right)$ and sum to the total number of electrons.

$$
\begin{equation*}
N_{\text {electron }}=\sum_{A}^{\text {atoms }} q^{(A)} \tag{2.56}
\end{equation*}
$$

4. NHOs and NBO Once the density matrix has been transformed to the NAOs basis, the NBO program will begin the search for an optimal natural Lewis structure. Firstly, NAOs of high occupancy ( $>1.999 \mathrm{e}$ ) are removed as unhybridized core orbitals $\left(C_{A}\right)$. The next step is to search for lone-pair eigenvectors $L_{A}$, which occupancy exceeds a preset pair threshold ( $\rho_{\text {threshold }}=1.90$ ) in one-center blocks $\Gamma^{(A)}$. The density matrix is depleted of eigenvectors satisfying this threshold, and the program then cycles over all two center blocks $\Gamma^{(A B)}$ searching for bond vector $b_{A B}$ whose occupancy exceeds $\rho_{\text {threshold }}$. The search may be further extended to three-center bonds if an insufficient number of electron pairs were found in the one- and two-center searches. The set of localized electron pairs $\left(C_{A}\right)^{2}\left(L_{A}\right)^{2}\left(b_{A B}\right)^{2}$ formed in this manner constitutes a "natural Lewis structure" to describe the system. The best NBO structure is that corresponding to the largest overall $\rho_{\text {Lewis }}$ and is generally formed to agree with the pattern of bonds and lone pairs of the chemist's standard Lewis formula.

Each bond-type $b_{A B}$ may be decomposed into its constituent normalized atomic hybrids $\left(\widetilde{h}^{(A)}, \tilde{h}^{(B)}\right)$ and polarization coefficients $\left(c^{(A)}, c^{(B)}\right)$.

$$
\begin{equation*}
b_{A B}=c^{(A)} \tilde{h}^{(A)}+c^{(B)} \tilde{h}^{(B)} \tag{2.5}
\end{equation*}
$$

Because of possible overlap of an initial bond orbital $\phi^{(A B)}$ with other bond orbitals $\phi^{(A C)}$, the hybrids are systematically reorthogonalized to produce the final set of NHOs $\left(h^{(A)}, h^{(B)}\right)$.
5. NLMOs The semi-localized NLMOs are obtained by slightly modifying the NBOs. The corresponding unitary transformation is found by zeroing the off-diagonal block $\Gamma_{i j}^{(A B)}$ of $\Gamma^{(A B)}$ by a Jocobi transformation, where A is strongly occupied (core, lone pairs, bonds) and B weakly occupied (antibond, Rydberg, etc.) in the NBO. The magnitudes of the NLMO mixing coefficients give a quantitative measure of the "resonance" delocalization leading to departures from a strictly localized "Lewis structure" NBO picture. ${ }^{32}$

### 2.4.3 Charge Decomposition Analysis (CDA)

The charge decomposition analysis (CDA) ${ }^{33}$ constructs the wave function of the complex in terms of the linear combination of the donor and acceptor fragment orbitals (LCFO). Three terms are then calculated for each LCFO orbital of the complex: (i) the charge donation $d$ given by the mixing of the occupied orbitals of the donor and the unoccupied orbitals of the acceptor; (ii) the back donation $b$ given by the mixing of the occupied orbitals of the acceptor and the unoccupied orbitals of the donor; (iii) the charge depletion from the overlapping area (charge polarization) $r$ given by mixing of the occupied orbitals of donor and acceptor. The sum of the three contributions gives the total amount of donation, back donation and charge polarization in the complex.

For example, for a molecule $A B$ with properly chosen fragments $A$ and $B$, the charge donation $d_{i}$ from fragment A to fragment B can then be defined as

$$
\begin{equation*}
d_{i}=\sum_{k}^{o c c, A} \sum_{n}^{v c c, B} m_{i} c_{k i} c_{n i}<\phi_{k}\left|\phi_{n}\right\rangle \tag{2.58}
\end{equation*}
$$

where the functions $\phi$ are atomic orbitals or any other basis set. For every orbital of the molecule, summation of $d_{i}$ leads to the overall charge donation from A to B . In a similar manner, back donation $b_{i}$ can be written as

$$
\begin{equation*}
b_{i}=\sum_{l}^{o c c, B} \sum_{m}^{v c c, A} m_{i} c_{l i} c_{m i}<\phi_{l}\left|\phi_{m}\right\rangle \tag{2.59}
\end{equation*}
$$

The closed shell interaction of the two fragments is then defined by

$$
\begin{equation*}
r_{i}=\sum_{k}^{o c c, A} \sum_{l}^{o c c, B} m_{i} c_{k i} c_{l i}<\phi_{k}\left|\phi_{l}\right\rangle \tag{2.60}
\end{equation*}
$$

The $r_{i}$ term is calculated from the overlap of the occupied region of the fragment orbitals and the sum of the $r_{i}$ term is always negative. That is, interactions between filled orbitals are repulsive. We can also call this term the charge polarization because it seems that $r_{i}$ gives the amount of electronic charge which is removed from the overlap of the occupied MOs into the nonoverlapping regions.

Chapter 3. Ligand Site Preference in Iron Tetracarbonyl Complexes

### 3.1 Introduction

The nature of the metal-CO bond in transition metal carbonyl and related complexes is commonly described by the Dewar-Chatt-Duncanson (DCD) model of synergistic $\mathrm{CO} \rightarrow$ metal $\sigma$-donation and $\mathrm{CO} \leftarrow$ metal $\pi$-back donation (Figure 3.1). ${ }^{34}$ This conceptual framework has been widely accepted in inorganic ${ }^{35}$ and organometallic ${ }^{2}$ chemistry and many properties of complexes with CO and other ligands can be easily classified or even predicted in terms of $\sigma$-donor $/ \pi$-acceptor interactions. ${ }^{36}$

Figure 3.1 Schematic representation of the dominant orbital interactions of transition metal carbonyls in terms of $\mathrm{CO} \rightarrow \mathrm{M} \sigma$-donation (top) and $\mathrm{CO} \leftarrow \mathrm{M} \pi$-back donation (bottom).

Quite recently, it was shown that the use of quantum chemical calculations in conjunction with charge partitioning schemes like the charge decomposition analysis (CDA) ${ }^{33}$ or Weinhold's natural bond orbital (NBO) approach ${ }^{29}$ support this model even at a more quantitative level. ${ }^{37-39}$ For example, it was shown that in a series of isoelectronic complexes $\mathrm{M}(\mathrm{CO})_{6}\left(\mathrm{M}=\mathrm{Hf}^{2-}, \mathrm{Ta}, \mathrm{W}, \mathrm{Re}^{+}, \mathrm{Os}^{2+}\right.$, and $\left.\mathrm{Ir}^{3+}\right)$ the $\mathrm{C}-\mathrm{O}$ stretching frequencies decrease with the extent of OC $\leftarrow$ metal $\pi$-back donation. ${ }^{39}$ In addition, it was also pointed out that the metal-CO bond length of carbonyl coordinated in trans position to various ligands L of $\mathrm{M}(\mathrm{CO})_{5} \mathrm{~L}(\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W})$ complexes is lengthened with increasing $\mathrm{L} \leftarrow$ metal $\pi$-back donation. ${ }^{37}$ Charge back donation is, however, not the only factor that determines stretching frequencies and
bond lengths to coordinated ligands. This is best illustrated by non-classical transition metal carbonyl complexes ${ }^{40}$ in which the wavenumbers of the $\mathrm{C}-\mathrm{O}$ stretching mode is larger for coordinated than for isolated CO. It was shown that this behaviour is not due to donor-acceptor interactions but due to polarizing effects exerted from the positively charged metal on coordinated CO. ${ }^{41}$

Whereas the actual virtue of charge partitioning schemes lies in the possibility of comparing $\sigma$-donor $/ \pi$-acceptor strengths of various ligands relative to each other, it does not predict which of these contributions is more important for the actual metalligand binding energy. Numerous earlier theoretical studies showed that in transition metal carbonyl complexes, $\mathrm{CO} \leftarrow \mathrm{M} \pi$-back donation is indeed more important for the binding energy than $\mathrm{OC} \rightarrow \mathrm{M} \sigma$-donation. ${ }^{42-44}$ However, quite recently it was pointed out that the interaction energy between metal carbonyl and CO fragments correlates with the increase of the stabilizing orbital interaction of these fragments, which in turn is dominated by their HOMO-LUMO contributions. ${ }^{39 b}$ In the aforementioned series of isoelectronic hexacarbonyl complexes of $\mathrm{Hf}^{2-}, \mathrm{Ta}, \mathrm{W}, \mathrm{Re}^{+}, \mathrm{Os}^{2+}$ and $\mathrm{Ir}^{3+}$ it was shown that the HOMO and the LUMO of the corresponding metal pentacarbonyl fragments are lowered on going from $\mathrm{Hf}^{2-}$ to $\mathrm{Ir}^{3+}$. Thus pentacarbonyl fragments with relatively high lying HOMOs (e.g. $\left.\mathrm{Hf}(\mathrm{CO})_{5}{ }^{2-}, \mathrm{W}(\mathrm{CO})_{5}\right)$ imply that $\pi$-back donation is more important for the $\mathrm{M}-\mathrm{CO}$ binding energy, whereas $\sigma$-donation dominates for those fragments with low lying LUMOs (e.g. $\mathrm{Ir}^{3+}$ ). ${ }^{39 \mathrm{~b}}$

Beside the aforementioned consequences of $\sigma$-donation and $\pi$-back donation another effect of varying donor-acceptor strengths originated in a generally applied rule for predicting the structures of transition metal carbonyls. Experimental evidence and qualitative molecular orbital considerations suggest that strong $\pi$ accepting ligands prefer the equatorial position of trigonal bipyramidal complexes containing $\mathrm{d}^{8}$ metals, while $\sigma$-donor ligands prefer axial coordination sites. ${ }^{45,46}$ This model is supported by a limited number of quantum chemical studies of complexes $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}\left(\mathrm{~L}=\mathrm{N}_{2},{ }^{47} \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4},{ }^{48} \mathrm{H}_{2},{ }^{49} \mathrm{PR}_{3}{ }^{50}\right.$ and $\left.\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}{ }^{51}\right)$. However, no systematic and comparative theoretical work with respect to a wider range of such complexes has been published so far. Moreover, the reason for the ligand site preference was not included. In the present study, a detailed and thorough examination of the bonding situation and the relative stability of complexes of the general type $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}(\mathrm{~L}=$
$\mathrm{CO}, \mathrm{CS}, \mathrm{N}_{2}, \mathrm{NO}^{+}, \mathrm{CN}^{-}, \mathrm{NC}^{-}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}, \mathrm{CF}_{2}, \eta^{2}-\mathrm{H}_{2}, \mathrm{NH}_{3}, \mathrm{NF}_{3}$, $\mathrm{PH}_{3}, \mathrm{PF}_{3}$ ) is therefore carried out. In particular, energetic and structural differences between axially and equatorially coordinated ligands $L$ are focused on and requisites leading to their preferred coordination site are addressed.

### 3.2 Theoretical Methods

Geometry optimizations and energy calculations were performed using Becke's three-parameter hybrid-functional in combination with the correlation functional according to Lee, Yang and Parr (B3LYP). ${ }^{52}$ A non-relativistic small-core effective core potential and a (441/2111/41) split-valence basis set were used for $\mathrm{Fe}^{27 \mathrm{c}}$ and an all-electron $6-31 \mathrm{G}(\mathrm{d})$ basis set was chosen for first- and second-row elements. ${ }^{53}$ An additional polarization function was used for the hydrogens in $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{H}_{2}{ }^{54}$ This combination of basis sets is further denoted as basis set II. ${ }^{55}$ All stationary points found on the potential energy surface were further characterized by numerical frequency analyses. An improved estimate for bond dissociation energies is obtained by single-point energy calculations on the B3LYP/II geometries using coupled-cluster theory with singles and doubles and a non-iterative estimate of triple substitution $(\operatorname{CCSD}(\mathrm{T})) .{ }^{21}$ All calculations used the program packages Gaussian 94/98, ${ }^{56}$ ACES II ${ }^{57}$ and MOLPRO 96/2000. ${ }^{58}$ Metal-ligand donor-acceptor interactions were examined in terms of charge donation, back donation and repulsive polarization using the program CDA $2.1^{59}$ and Weinhold's NBO analysis ${ }^{29}$ as implemented in Gaussian98. ${ }^{56 \mathrm{~b}}$

### 3.3 Results and Discussion

Figure 3.2 shows the optimized geometries of the complexes $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{1})$, singlet and triplet $\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{2 a}, \mathbf{2 b})$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ where L is $\mathrm{CS}(\mathbf{3 a}, \mathbf{3 b}), \mathrm{N}_{2}(\mathbf{4 a}$, $\mathbf{4 b}), \mathrm{NO}^{+}(\mathbf{5 a}, \mathbf{5 b}), \mathrm{CN}^{-}(\mathbf{6 a}, \mathbf{6 b}), \mathrm{NC}^{-}(7 \mathbf{a}, 7 \mathbf{b}), \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}(\mathbf{8 a}, 8 \mathbf{8}), \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}(\mathbf{9 a}, 9 \mathbf{9})$, $\mathrm{CCH}_{2}(10 a, 10 b), \mathrm{CH}_{2}(11 a, 11 b), \mathrm{CF}_{2}(12 a, 12 b), \eta^{2}-\mathrm{H}_{2}(13 a, 13 b), \mathrm{NH}_{3}(14 a, 14 b)$, $\mathrm{NF}_{3}(\mathbf{1 5 a}, \mathbf{1 5 b}), \mathrm{PH}_{3}(\mathbf{1 6 a}, \mathbf{1 6 b})$ or $\mathrm{PF}_{3}(\mathbf{1 7 a}, \mathbf{1 7 b})$ coordinated either at an axial or equatorial site (Scheme 3.1).

Table 3.1 Calculated Relative Energies $\mathrm{E}_{\text {rel }}{ }^{\mathrm{a}}$ and Bond Dissociation Energies $\mathrm{D}_{\mathrm{e}}$ and $\mathrm{D}_{0}$ with Respect to Singlet $\mathrm{Fe}(\mathrm{CO})_{4}$ and Singlet $\mathrm{L}\left(\mathrm{L}=\mathrm{CO}, \mathrm{CS}, \mathrm{N}_{2}, \mathrm{NO}^{+}, \mathrm{CN}^{-}\right.$, NC $\left., \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}{ }^{\mathrm{b}}, \mathrm{CF}_{2}, \eta^{2}-\mathrm{H}_{2}, \mathrm{NH}_{3}, \mathrm{NF}_{3}, \mathrm{PH}_{3}, \mathrm{PF}_{3}\right)$.

All energies are in kcal mol ${ }^{-1}$. ${ }^{a}$ relative to the axial isomer and without zero-point energy
(ZPE) correction. ${ }^{b}$ triplet $\mathrm{CH}_{2}$. ${ }^{c}$ ZPE correction obtained at the B3LYP/II level of theory.

axial

equatorial

Scheme 3.1 Schematic representation of the axial (left) and equatorial isomer (right) of (CO) ${ }_{4} \mathrm{FeL}$.

Relative energies and (CO) ${ }_{4} \mathrm{Fe}-\mathrm{L}$ bond dissociation energies without and with zero-point energy corrections ( $D_{e}$ and $D_{o}$, respectively) are summarized in Table 3.1. These values are calculated using total energies $\mathrm{E}_{\text {total }}$ without and with zero-point energy corrections obtained either at the B3LYP/II//B3LYP/II or $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II} / \mathrm{B} 3 \mathrm{LYP} / \mathrm{II}$ level of theory (eq 3.1). Due to the interest in spin-allowed dissociation processes, these values were derived only with respect to the singlet ground states of $\mathrm{Fe}(\mathrm{CO})_{4}$ and ligands $\mathrm{L} .{ }^{60}$

$$
\begin{equation*}
\mathrm{D}_{\mathrm{e} / \mathrm{o}}=\mathrm{E}_{\text {total }}\left[\mathrm{Fe}(\mathrm{CO})_{4}\right]+\mathrm{E}_{\text {total }}[\mathrm{L}]-\mathrm{E}_{\text {total }}\left[\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}\right] \tag{3.1}
\end{equation*}
$$

Frequency analyses show that iron tetracarbonyl complexes with the axial ligands ethylene (8a), acetylene (9a), vinylidene (10a), carbene (11a) and difluorcarbene (12a) are transition states on their respective potential energy surface rather than local minima. A direct comparison between these complexes and their corresponding equatorial isomers, particularly with respect to the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{L}$ bond dissociation energies, therefore does not seem appropriate.

According to the calculations (B3LYP/II/B3LYP/II) side-on $\left(\eta^{2}\right)$ coordination of the diatomic ligands $\mathrm{CS}, \mathrm{N}_{2}$, and $\mathrm{NO}^{+}$result in complexes that are significantly less stable than their respective end-on counterparts. These structures are thus not discussed in detail. Furthermore, with the exception of cyanide and isocyanide complexes, only the energetically most stable linkage isomers of complexes containing potential ambidentate ligands are focused on.

Unless otherwise noted, only the bond dissociation energies $\mathrm{D}_{0}$ obtained at the highest level of theory, namely $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II} /$ B3LYP/II, are referred to. Bond dissociation energies are not corrected for the basis set superposition error (BSSE). ${ }^{61}$

${ }^{a} \mathrm{~L} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation. $\quad{ }^{\mathrm{b}} \mathrm{L} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4} \pi$-back donation. $\quad{ }^{\mathrm{c}} \mathrm{L} \leftrightarrow \mathrm{Fe}(\mathrm{CO})_{4}$ repulsive polarization. ${ }^{d}$ residual term $\Delta .{ }^{e}$ partial charge of $\mathrm{Fe}(\mathrm{CO})_{4} .{ }^{f}$ charge donation involving valence $\sigma$-orbitals of the ligand. ${ }^{g}$ charge-back donation expressed as the natural occupancy of the valence $\mathrm{p}-\pi$ orbitals of ligand L .

Within the CDA partitioning scheme, the donor-acceptor strengths of the various ligands L are classified by the relative amounts of $\mathrm{L} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation (d), $\mathrm{L} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4} \pi$-back donation (b) and $\mathrm{L} \leftrightarrow \mathrm{Fe}(\mathrm{CO})_{4}$ charge repulsion (r) between the ligand L and the remaining complex fragment $\mathrm{Fe}(\mathrm{CO})_{4}$. These charge contributions together with the residual term $\Delta$ are summarized in Tables 3.2 and 3.3. Note, that $\Delta \approx 0$ holds for all complexes considered in this study indicating that the interpretation of the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{L}$ bonds in terms of $\sigma$-donor $/ \pi$-acceptor interactions is indeed justified. ${ }^{38,62}$ Furthermore, it should be emphasized that more complete basis sets like $\operatorname{TZ2P}$ or $6-31 \mathrm{G}(\mathrm{d}, \mathrm{p})$ do not change the relative ratio of the charge components significantly. ${ }^{33}$ Under certain circumstances, however, the known basis set dependence of the CDA may yield inconsistent results and the use of this partitioning scheme as a 'black-box' tool is not advisable at this stage. ${ }^{51}$

The results of the NBO analyses are summarized in Table 3.2. The chargeback donation $\mathrm{q}(\pi) \mathrm{L}$ of ligand L is expressed as the difference of the $\mathrm{p}(\pi)$ populations between the coordinated and isolated ligand with frozen complex geometry. The difference between $\mathrm{q}(\pi) \mathrm{L}$ and the partial charge of the complex fragment $\mathrm{Fe}(\mathrm{CO})_{4}$ is then used as a measure of the charge-donation $q(\sigma) \mathrm{L}$.

### 3.3.2 $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{1})$ and $\mathrm{Fe}(\mathrm{CO})_{4}$ (2)

The equatorial $\mathrm{Fe}-\mathrm{CO}$ distance of $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{1})$ is found to be shorter than the axial one (Fig 3.2.1). The respective bond lengths of $1.805 \AA$ and $1.819 \AA$ are in very good agreement with X-ray crystallographic data. ${ }^{63}$ Similarly, the $\mathrm{C}-\mathrm{O}$ bond lengths of $1.151 \AA$ and $1.147 \AA$ found for axial and equatorial CO are also in accord with the experiment. ${ }^{63}$ Due to contradictory experimental ${ }^{64-67}$ and theoretical results ${ }^{44,68-73}$ an unequivocal assignment of the relative $\mathrm{Fe}-\mathrm{CO}$ bond lengths of $\mathrm{Fe}(\mathrm{CO})_{5}$ is, however, still somewhat ambiguous.

Figure 3.2.1 Optimized geometries (B3LYP/II) of $\mathrm{Fe}(\mathrm{CO})_{5}$. Bond lengths are given in $\AA$.

$2 a$

Figure 3.2.2 Optimized geometries (B3LYP/II) of $\mathrm{Fe}(\mathrm{CO})_{4}$, singlet (2a) and triplet (2b). Bond lengths are given in $\AA$, bond angles in degree.

The first bond dissociation energy $\mathrm{D}_{\mathrm{o}}$ of CO for $\mathbf{1}$ is calculated to be 45.1 kcal $\mathrm{mol}^{-1}$. Although this value does not differ significantly from the previous estimate ${ }^{70}$ it converges nicely to the experimental value of $41 \pm 2 \mathrm{kcal} \mathrm{mol}^{-174}$ and is also in line with other calculations. ${ }^{44,47,69}$

The total amount of $\mathrm{OC} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation and $\mathrm{OC} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4} \pi$-back donation obtained from CDA and NBO analysis clearly show that CO is a stronger $\sigma-$ donor than $\pi$-acceptor with respect to the charge transferred between complex fragment $\mathrm{Fe}(\mathrm{CO})_{4}$ and the carbonyl ligand. The ability of CO to act as a $\sigma$-donor is slightly more pronounced when it is coordinated in an axial position, whereas its $\pi$ -
acceptor capabilities are almost independent from the coordination site. Table 3.3 shows the partitioning of the electronic interaction between $\mathrm{Fe}(\mathrm{CO})_{4}$ and CO into explicit orbital contributions. It is evident that $\mathrm{OC} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation occurs via orbitals of $a_{1}{ }^{\prime}$ and $a_{2} "$ symmetry suggesting the main charge transfer from occupied $\mathrm{CO}(\sigma)$ to vacant $\mathrm{Fe}(\mathrm{d}), \mathrm{Fe}(\mathrm{s})$ and $\mathrm{Fe}(\mathrm{p})$ orbitals. On the other hand, $\mathrm{OC} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4} \pi$ back donation is dominated by orbitals of $e^{\prime}$ and $e^{\prime \prime}$ symmetry implying charge transfer from occupied $\mathrm{Fe}(\mathrm{d})$ into vacant $\mathrm{CO}\left(\pi^{*}\right)$ orbitals. Interestingly, there is also a substantial amount of $\mathrm{OC} \leftrightarrow \mathrm{Fe}(\mathrm{CO})_{4}$ repulsive polarization involving orbitals of $\mathrm{a}_{2}{ }^{\prime \prime}$ (axial CO) and - to a lesser extend - e' and e" (equatorial CO) symmetry.

### 3.3.3 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CS}$ (3)

The thiocarbonyl iron tetracarbonyl complex $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CS}$ was first synthesized by Petz and co-workers and has been extensively studied by this group since that time. ${ }^{75}$ The Fe-CS bond length of axial (3a) and equatorial (3b) thiocarbonyl are calculated to be $1.787 \AA$ and $1.779 \AA$, respectively. The $\mathrm{C}-\mathrm{S}$ bond lengths of coordinated thiocarbonyl are $1.551 \AA(\mathbf{3 a})$ and $1.559 \AA(\mathbf{3 b})$ and thus slightly longer than the corresponding value of isolated thiocarbonyl, which is calculated to be 1.548 $\AA$. The closely related complex $\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{PPh}_{3}\right)_{2} \mathrm{CS}$ has $\mathrm{Fe}-\mathrm{CS}$ and $\mathrm{C}-\mathrm{S}$ bond lengths of $1.768 \AA$ and $1.563 \AA,{ }^{76}$ respectively, in reasonable agreement with the calculated values.

3a

3b

Figure 3.2.3 Optimized geometries (B3LYP/II) of (CO) $)_{4} \mathrm{FeCS}$, axial (3a) and equatorial (3b) isomers. Bond lengths are given in $\AA$, bond angles in degree.

The ( CO$)_{4} \mathrm{Fe}-\mathrm{CS}$ bond dissociation energy of $64.2 \mathrm{kcal} \mathrm{mol}^{-1}$ is the same for the axial (3a) and equatorial (3b) isomer. This situation is reflected by IR and NMR data ${ }^{75 \mathrm{a}}$ suggesting that experimentally observed $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CS}$ is indeed a mixture of the two isomers. The comparison between the experimental and theoretical frequencies values is shown for 3a and 3b in Table 3.4. Two C-S bands of 1320 and $1305 \mathrm{~cm}^{-1}$ in IR spectrum are observed. ${ }^{75 a}$ The higher frequency is assigned to $\mathbf{3 a}$. The lower one must belong to C-S for 3b. The calculated frequencies of 1341 for 3a and 1324 $\mathrm{cm}^{-1}$ for 3b are in excellent agreement with experimental results. The C-O bands are also comparable between calculated and measured data. It is noteworthy that the bond dissociation energy of $\mathbf{3}$ is significantly increased compared to the $(\mathrm{CO})_{4} \mathrm{Fe}-$ CO bond strength of $\mathbf{1}$. Other arrangements of the thiocarbonyl ligand were found to be energetically highly unfavourable. ${ }^{77}$

According to the CDA results, thiocarbonyl is a slightly stronger $\sigma$-donating than $\pi$-accepting ligand. The difference of these charge contributions is, however, small and with regard to the negligible energy difference of $0.1 \mathrm{kcal} \mathrm{mol}^{-1}$ between isomers $\mathbf{3 a}$ and $\mathbf{3 b}$, one could conclude that there is no distinct ligand site preference of CS due to almost equal amounts of $\sigma$-donation and $\pi$-back donation. Although the NBO analysis deviates sporadically from this results (e.g. in 3b CS is predicted to be
a slightly better $\pi$-acceptor than $\sigma$-donor), this does not change the indecisive character of CS with respect to the coordination site. Both partitioning approaches thus agree in that CS is a better $\pi$-acceptor than CO.

### 3.3.4 $\mathrm{Fe}(\mathrm{CO})_{4} \mathbf{N}_{2}$ (4)

4a

4b

Figure 3.2.4 Optimized geometries (B3LYP/II) of (CO) $4_{4} \mathrm{Fe} \mathrm{N}_{2}$, axial (4a) and equatorial (4b) isomers . Bond lengths are given in $\AA$, bond angles in degree.

The structures of axial ( $\mathbf{4 a}$ ) and equatorial ( $\mathbf{4} \mathbf{b}$ ) dinitrogen iron tetracarbonyl $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~N}_{2}$ show $\mathrm{Fe}-\mathrm{N}_{2}$ bond lengths of $1.912 \AA$ and $1.907 \AA$, respectively. ${ }^{78}$ This contrasts the results of Radius et al., ${ }^{47}$ who predict that the $\mathrm{Fe}-\mathrm{N}_{2}$ bond length of axial $\mathrm{N}_{2}$ is shorter than of equatorial $\mathrm{N}_{2}$. The small energy difference of $0.5 \mathrm{kcal} \mathrm{mol}^{-1}$ between $\mathbf{4 a}$ and $\mathbf{4 b}$, is in favour of the axial isomer, again opposite to the trend suggested by the same group, which is based on bond dissociation enthalpies. ${ }^{47}$ Although, the reaction of $\mathrm{Fe}(\mathrm{CO})_{5}$ with $\mathrm{N}_{2}$ in polyethylene film implies that $\mathrm{N}_{2}$ may occupy an equatorial rather an axial coordination site, ${ }^{79}$ photolysis experiments of $\mathrm{Fe}(\mathrm{CO})_{5}$ in nitrogen-containing matrices ${ }^{60 \mathrm{a}, \mathrm{c}}$ show an opposite behaviour, that is a more stable axial than equatorial isomer. The calculated energy difference is, however, too small to provide a reasonable and conclusive solution to these contradictory experimental results.

Mössbauer spectra of several dinitrogen complexes, ${ }^{80}$ suggest that $\mathrm{N}_{2}$ is a stronger $\pi$-acceptor than $\sigma$-donor. Whereas this is certainly true for complexes $\mathrm{M}(\mathrm{CO}){ }_{5} \mathrm{~N}_{2}(\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W})$, it does not apply for $\mathrm{Ni}(\mathrm{CO})_{3} \mathrm{~N}_{2} .{ }^{37}$ In the present case, the CDA and NBO results both yield a consistent trend predicting the extend of $\mathrm{N}_{2} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4} \pi$-back donation to be somewhat smaller than $\mathrm{N}_{2} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation. The difference in the extend of $\sigma$-donation and $\pi$-back donation is, however,
negligible and in conjunction with the very small energy difference between the isomers, there is no pronounced tendency of $\mathrm{N}_{2}$ to coordinate either into an axial or equatorial coordination site. For the equatorial isomer $\mathbf{4 b}$ the NBO method even gives exactly the same numerical value for $\sigma$-donation and $\pi$-back donation.

### 3.3.5 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NO}^{+}(5)$

It is found that axial $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NO}^{+}(\mathbf{5 a})$ is considerably less stable than its equatorial isomer (5b) by $20.7 \mathrm{kcal} \mathrm{mol}^{-1}$ indicating a strong preference of coordination at the equatorial rather than axial site. The $\mathrm{Fe}-\mathrm{NO}^{+}$bond length of equatorial $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NO}^{+}(\mathbf{5 b})$ is calculated to be $1.695 \AA$ and compared to its $\mathrm{Fe}-\mathrm{CO}$ bond lengths of $1.879 \AA$ and $1.869 \AA$ shorter by approximately $0.2 \AA$. This difference and the absolute bond lengths are in good agreement with experimental findings of the closely related $\mathrm{Fe}(\mathrm{CO})_{2}(\mathrm{NO})_{2}$ complex: the deviations are less than $0.014 \AA .^{81}$ The $\mathrm{Fe}-\mathrm{NO}^{+}$bond dissociation energy $\mathrm{D}_{0}$ is $105.1 \mathrm{kcal} \mathrm{mol}^{-1}$ indicating the strongest $\mathrm{Fe}-\mathrm{L}$ bond of all complexes studied in this work. ${ }^{82}$

5a

5b

Figure 3.2.5 Optimized geometries (B3LYP/II) of $(\mathrm{CO})_{4} \mathrm{Fe} \mathrm{NO}^{+}$, axial (5a) and equatorial ( $\mathbf{5 b}$ ) isomers. Bond lengths are given in $\AA$, bond angles in degree.

The results from both charge partitioning approaches show that $\mathrm{NO}^{+}$is a very poor $\sigma$-donor but at the same time an excellent $\pi$-acceptor. In fact, the NBO data even suggest the extent of $\pi$-back donation to be almost five times larger than the
extent of $\sigma$-donation. The reason is clear that the positive charge of the ligand lowers its orbital energies, which in turn alleviates $\pi$-backdonation significantly (Scheme 3.2). In conjunction with the large energy difference between $\mathbf{5 a}$ and $\mathbf{5 b}$ this convincingly demonstrates a pronounced tendency to coordinate in an equatorial coordination site.

Scheme 3.2 Schematic representation of the relative energy for HOMO and LUMO in free two-atom ligand molecules at the B3LYP/II level.

### 3.3.6 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CN}^{-}$(6) and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NC}^{-}$ <br> (7)

In a previous paper, it was reported that $\mathrm{M}-\mathrm{CN}^{-}$and $\mathrm{M}-\mathrm{NC}^{-}$bonds are rather strong for transition metals of group 6 and $10 .{ }^{37}$ The extension of these studies to analogous iron complexes shows that $\mathrm{Fe}-\mathrm{CN}^{-}$and $\mathrm{Fe}-\mathrm{NC}^{-}$bonds also have remarkably high bond dissociation energies ranging from 72.7 to $96.5 \mathrm{kcal} \mathrm{mol}^{-1}$. Except for axial $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CN}^{-}(\mathbf{6 a})$, the bond dissociation energies are, however, smaller than those of corresponding $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NO}^{+}$isomers. This is also reflected by the $\mathrm{Fe}-\mathrm{CN}^{-}$and $\mathrm{Fe}-\mathrm{NC}^{-}$bonds, which are significantly elongated by $0.3 \AA$ compared
to their corresponding $\mathrm{NO}^{+}$analogues. Note, that the bond dissociation energy is always higher for $\mathrm{Fe}-\mathrm{CN}^{-}$than for $\mathrm{Fe}-\mathrm{NC}$.

$6 \mathbf{a}$

$7 \mathbf{a}$

6b

7b

Figure 3.2.6 Optimized geometries (B3LYP/II) of (CO) $)_{4} \mathrm{FeCN}^{-}$and $(\mathrm{CO})_{4} \mathrm{FeNC}$, axial $(\mathbf{6 a}, 7 \mathbf{7 a})$ and equatorial $(\mathbf{6 b}, \mathbf{7 b})$ isomers. Bond lengths are given in $\AA$, bond angles in degree.

For the linkage isomers $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CN}^{-}(\mathbf{6 a}$ and $\mathbf{6 b})$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NC}^{-}(\mathbf{7 a}$ and $\mathbf{7 b})$ only axially coordinated cyanide/isocyanide leads to the energetically most favoured complex. The energy differences favouring the axial isomers are $6.7 \mathrm{kcal} \mathrm{mol}^{-1}$ for the cyanide and $6.3 \mathrm{kcal} \mathrm{mol}^{-1}$ for the isocyanide complex. For the cyanide complex,
this relative stability is supported by the crystallographic data of $\left[\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CN}\right]\left[\mathrm{N}\left(\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right)\right]$ in which the $\left[\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CN}\right]^{-}$moiety forms a distorted trigonal bipyramid. ${ }^{83}$ As expected, the calculated bond lengths of the $\mathrm{Fe}-\mathrm{CN}$ bond and of the axial and equatorial $\mathrm{Fe}-\mathrm{CO}$ bonds are somewhat larger compared to their corresponding values measured in a crystal environment. The differences are, however, in an acceptable range of 0.02 to $0.05 \AA$.

With respect to the cyanide/isocynaide donor-acceptor strength, CDA and NBO results present a consistent picture indicating that $\mathrm{CN}^{-}$as well as $\mathrm{NC}^{-}$show an opposite behaviour compared with $\mathrm{NO}^{+}$. Thus, an extremely pronounced extend of $\sigma$-donation combined with an almost vanishing amount of $\pi$-back donation is predicted for these ligands. The remarkable site preference, which governs the ligands in axial coordination sites of pentacoordinated iron complexes is nicely resembled by the energy difference that favours the axial isomers 6a and 7a over the equatorial isomers $\mathbf{6 b}$ and $\mathbf{7 b}$, respectively.

### 3.3.7 $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}\right)$ (8) and $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}\right)$ (9)

The bond dissociation energy $D_{0}$ of the equatorial $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}\right)$ isomer $\mathbf{8 b}$ is $39.2 \mathrm{kcal} \mathrm{mol}^{-1}$ and close to the experimental value of $37.2 \mathrm{kcal} \mathrm{mol}^{-184}$ and other theoretical data. ${ }^{48}$ The calculated $\mathrm{Fe}-\mathrm{C}_{\text {ethylene }}$ bond lengths of $2.145 \AA$ resembles the experimental value of $2.117 \AA$ based on microwave spectra reasonably well. ${ }^{85}$ Other structural parameters like the axial and equatorial $\mathrm{Fe}-\mathrm{CO}$ bond lengths or the ethylenic $\mathrm{C}-\mathrm{C}$ bond lengths of coordinated ethylene are in particular good agreement with experimental data and differ by less than $0.015 \AA \AA^{85}$

The corresponding acetylene complex $9 \mathbf{b}$ has a calculated bond dissociation energy $\mathrm{D}_{0}$ of $37.3 \mathrm{kcal} \mathrm{mol}^{-1}$. The $\mathrm{Fe}-\mathrm{C}_{\text {acetylene }}$ bond lengths is $2.097 \AA$ which is in line with the experimental value of $2.048 \AA$ reported for the related $\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{POMe}_{3}\right)\left(\eta^{2}-\mathrm{C}_{2} \mathrm{Ph}_{2}\right)$ complex. ${ }^{86}$ The same holds for the bond length of the acetylenic C-C bond, which is calculated to be $1.259 \AA$ (exp. $1.263 \AA$ )..${ }^{86}$ At the B3LYP/II level, we find that the $\mathrm{C}-\mathrm{C}$ triple bond is slightly lengthened upon complex formation by about $0.06 \AA$ implying a decrease in its bond order.

9a

8b

9b

Figure 3.2.7 Optimized geometries (B3LYP/II) of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{C}_{2} \mathrm{H}_{4}\right)$ and $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{C}_{2} \mathrm{H}_{2}\right)$, axial $(\mathbf{8 a}, 9 \mathbf{9})$ and equatorial $(\mathbf{8 b}, 9 \mathbf{b})$ isomers. Bond lengths are given in $\AA$, bond angles in degree.

For ethylene and acetylene it is found that $\sigma$-donation dominates over $\pi$-back donation, which is consistent with previous theoretical results. ${ }^{38,51}$ Surprisingly, this trend objects the generally applied rule for predicting the site preference of ligands that are strong $\sigma$-donors. ${ }^{45,46}$ According to this, ethylene as well as acetylene should prefer an axial rather than an equatorial coordination site. We find, however that the axial isomers $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}\right)(\mathbf{8 a})$ and $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}\right)(\mathbf{9 a})$ are substantially less stable than their equatorial counterparts by 8.6 and $10.7 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. In fact, the axial isomers are even found to represent transition states rather than local minima. Corresponding NBO data do not solve this discrepancy either, because the charge contributions obtained from this approach are not meaningful due to
indistinguishable $\sigma$-donating $/ \pi$-accepting orbitals. Therefore, no definite classification of the ligand site preference in terms of a $\sigma$-donation $/ \pi$ back donation scheme is possible within the present approach.

Note that although the absolute values of $\sigma$-donation and $\pi$-back donation are somewhat larger for the acetylene complex than for the ethylene complex, this does not imply that the bond dissociation energy for $\mathrm{Fe}-\mathrm{C}_{\text {acetylene }}$ is higher than the bond dissociation energy of $\mathrm{Fe}-\mathrm{C}_{\text {ethylene. }} .{ }^{38}$

### 3.3.8 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CCH}_{2}$

The calculated $\mathrm{Fe}-\mathrm{C}_{\text {vinylidene }}$ bond length of $\mathbf{1 0 b}$ is $1.780 \AA$, which is consistent with experimental values ranging from $1.74 \AA$ to $1.80 \AA$ found for related complexes. ${ }^{87}$ Similarly, the calculated $\mathrm{C}-\mathrm{C}$ distance of $1.310 \AA$ is also in reasonable agreement with experimental values in the range of $1.26 \AA$ to $1.33 \AA{ }^{\circ} .^{87}$

Figure 3.2.8 Optimized geometries (B3LYP/II) of (CO) $)_{4} \mathrm{Fe}\left(\mathrm{CCH}_{2}\right)$, axial (10a) and equatorial ( $\mathbf{1 0 b}$ ) isomers. Bond lengths are given in $\AA$, bond angles in degree.

The bond dissociation energy of the $\mathrm{Fe}-\mathrm{CCH}_{2}$ bond is calculated to be 83.8 $\mathrm{kcal} \mathrm{mol}^{-1}$ and is thus comparable in strength to the corresponding $\mathrm{Fe}-\mathrm{CN}^{-}$bond. The CDA results imply that the vinylidene ligand is a significantly better $\sigma$-donor than $\pi$ -
acceptor. This, however, does not result in a distinct preference of the axial isomer. In fact, axial $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CCH}_{2}(\mathbf{1 0 a})$ is found to be a transition state structure and less stable than its corresponding equatorial isomer (10b) by $8.7 \mathrm{kcal} \mathrm{mol}^{-1}$. The data from the corresponding NBO analysis, on the other hand suggest an opposite $\sigma$ donor $/ \pi$-acceptor behaviour, that is, vinylidene acting as a somewhat stronger $\pi$ acceptor than $\sigma$-donor. With respect to the relative stabilities of the two isomers this is in agreement with the general classification of a stronger $\pi$-accepting ligand preferring an equatorial coordination site. ${ }^{45,46}$

### 3.3.9 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CH}_{2}(\mathbf{1 1})$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CF}_{2}(\mathbf{1 2})$

11a

12a

11b

12b

Figure 3.2.9 Optimized geometries (B3LYP/II) of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{CH}_{2}\right)$ and $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{CF}_{2}\right)$, axial (11a, 12a) and equatorial (11b, 12b) isomers. Bond lengths are given in $\AA$, bond angles in degree.

The $\mathrm{Fe}-\mathrm{CH}_{2}$ bond length of equatorial carbene iron tetracarbonyl 11b is calculated to be $1.826 \AA$ and significantly shorter than the experimental values ranging from $2.001-2.010 \AA$ reported for hetero substituted, electron-rich carbene iron tetracarbonyl complexes. ${ }^{88}$ Note, however, that the calculated iron-carbene bond length is still substantially larger than the experimental iron-carbyne bond of $1.734 \AA$ reported for $\left[(\mathrm{CO})_{3} \mathrm{PPh}_{3} \mathrm{FeC}\left(\mathrm{N} i-\mathrm{Pr}_{2}\right)\right]^{+89}$

The iron-carbene bond length of difluorocarbene iron tetracarbonyl 12b is shorter by $0.004 \AA$ than its corresponding $\mathrm{Fe}-\mathrm{CH}_{2}$ bond analogue. The calculated bond dissociation energies $D_{0}$ of $87.4 \mathrm{kcal} \mathrm{mol}^{-1}$ (11b) and $64.3 \mathrm{kcal} \mathrm{mol}^{-1}$ ( $\mathbf{1 2 b}$ ) reveal an interesting feature of the complexes: the shorter bond found for $\mathbf{1 2 b}$ does not necessarily imply a stronger bond. The same trend is also revealed when comparing the comparatively short $\mathrm{Fe}-\mathrm{CO}$ bond lengths of $\mathbf{1}$ (1.805 $\AA$ ) with the longer $\mathrm{Fe}-\mathrm{CH}_{2}$ and $\mathrm{Fe}-\mathrm{CF}_{2}$ bonds of 11b and 12b. Such an inversed correlation has been found before and was explained by the hybridization of the donor lone-pair orbital. ${ }^{90}$ A higher s-character results in a more compact and more tightly bound donor lone-pair orbital. Whereas the former effect tends to shorten the donoracceptor bond, the latter leads to a less pronounced donor-acceptor interaction yielding a weaker bond. With respect to our calculated bond dissociation energies this implies that the donor lone-pair orbital of the $\mathrm{CF}_{2}$ ligand has a higher s-character than $\mathrm{CH}_{2}$, and that the donor lone-pair of CO has an even higher s-character than $\mathrm{CF}_{2}$. This, however, is in perfect agreement with the NBO data. ${ }^{91}$

As it was shown for analogous $\mathrm{W}(\mathrm{CO})_{5} \mathrm{CH}_{2}$ and $\mathrm{W}(\mathrm{CO})_{5} \mathrm{CF}_{2}$ complexes, ${ }^{38 \mathrm{c}}$ the CDA suggests that both carbene ligands are better $\sigma$-donors than $\pi$-acceptors. This, however, does not match with the relative stabilities of the axial and equatorial isomers in that the axial isomers $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CH}_{2}(\mathbf{1 1 a})$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CF}_{2}$ (12a) represent transition states, which are less stable than their corresponding equatorial counterparts (11b and 12b) by 8.3 and $4.6 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. Referring to the corresponding NBO data, however, suggests that $\mathrm{CH}_{2}$ as well as $\mathrm{CF}_{2}$ are slightly better $\pi$-acceptors than $\sigma$-donors. Although the numerical differences in these charge contributions are comparatively small they are still consistent with an energy wise more stable equatorial than axial isomer.

### 3.3.10 $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{H}_{2}\right)(13)$

A recent theoretical examination reports on equatorial $\eta^{2}$-dihydrogen iron tetracarbonyl and its relevance to the water gas shift reaction. ${ }^{49}$ It was found that the energy difference between this complex and the classical dihydride complex is quite small, with the latter isomer being more stable by $8-12 \mathrm{kcal} \mathrm{mol}^{-1} .{ }^{49}$ In this paper I focus only on $\eta^{2}$-dihydrogen isomers in which molecular hydrogen is either bound in an axial (13a) or equatorial (13b) coordination site. In both isomers, the $\mathrm{H}-\mathrm{H}$ bond length of coordinated $\mathrm{H}_{2}$ is calculated to be in the range of $0.8-0.9 \AA$. This resembles the value of free $\mathrm{H}_{2}$ quite closely indicating that these complexes indeed contain molecular hydrogen rather than two hydrides. From an energetic point of view, the difference between axial and equatorial coordination of $\mathrm{H}_{2}$ is small and the $\mathrm{Fe}-\mathrm{H}_{2}$ bond dissociation energies differ by only $1.6 \mathrm{kcal} \mathrm{mol}^{-1}$. The calculated bond dissociation energies of $16.5(\mathbf{1 3 a})$ and $18.5 \mathrm{kcal} \mathrm{mol}^{-1}(\mathbf{1 3 b})$ are the smallest found in this study and comparable in size to analogous bond values calculated for complexes of the general type $\mathrm{M}(\mathrm{CO})_{5}\left(\eta^{2}-\mathrm{H}_{2}\right)(\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W}) .{ }^{92}$

13a

13b

Figure 3.2.10 Optimized geometries (B3LYP/II) of (CO) ${ }_{4} \mathrm{Fe}\left(\mathrm{H}_{2}\right)$, axial (13a) and equatorial (13b) isomers. Bond lengths are given in $\AA$, bond angles in degree.

The CDA results show a non-negligible amount of $\pi$-back donation for both the axial as well as the equatorial isomers and a dominant charge contribution due to $\mathrm{H}_{2} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4} \sigma$-donation. Consideration of an energetically favoured equatorial isomer 13b leads to the same discrepancy found before for the corresponding acetylene and ethylene iron tetracarbonyl complexes. Suitable NBO data are not available for coordinated molecular hydrogen and thus an unequivocal characterization of the $\eta^{2}-\mathrm{H}_{2}$ in terms of its relative $\sigma$-donor/ $\pi$-acceptor strengths is not possible at this stage.

### 3.3.11 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NH}_{3}(\mathbf{1 4})$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{NF}_{3}(\mathbf{1 5})$

14a

15a

14b

15b

Figure 3.2.11 Optimized geometries (B3LYP/II) of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{NH}_{3}\right)$ and $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{NF}_{3}\right)$, axial $(\mathbf{1 4 a}, \mathbf{1 5 a})$ and equatorial $(\mathbf{1 4 b}, \mathbf{1 5 b})$ isomers. Bond lengths are given in $\AA$, bond angles in degree.

For both complexes the axial isomers (14a and 15a) are more stable than their equatorial pendants ( $\mathbf{1 4 b}$ and $\mathbf{1 5 b}$ ). which agrees with crystallographic data ${ }^{93}$ and IR spectra of related compounds. ${ }^{93,94}$ The calculated differences in energy are 6.4 and $3.0 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively, implying a clear preference of these ligands towards axial coordination sites. The estimates for the $\mathrm{Fe}-\mathrm{NH}_{3}$ and $\mathrm{Fe}-\mathrm{NF}_{3}$ bond dissociation energies are 39.1 and $23.5 \mathrm{kcal} \mathrm{mol}^{-1}$. These values are significantly smaller than those found for the $\mathrm{Fe}-\mathrm{CO}$ bond in $\mathbf{1}$, and are consistent with the experimentally observed low stability of such iron-amine complexes. ${ }^{95}$ The comparatively long $\mathrm{Fe}-$ N bond lengths in the axial isomers of $2.098 \AA$ (14a) and 2.011 (15a) with respect to that of $\mathrm{Fe}-\mathrm{C}$ in 1, respectively, are also consistent with low bond dissociation energies.
$\mathrm{NH}_{3}$ and $\mathrm{NF}_{3}$ are found to be stronger $\sigma$-donors than $\pi$-acceptors. For both ligands, the CDA yields $\pi$-back donations that are effectively zero. Based on the corresponding NBO data and previous studies, ${ }^{96}$ it is thus justified to take $\mathrm{NH}_{3}$ as an almost pure $\sigma$-donor. This bonding situation hardly changes when going to $\mathrm{NF}_{3}$ and the only apparent difference is a slightly increased amount of $\pi$-back donation.

### 3.3.12 $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PH}_{3}(16)$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PF}_{3}(17)$

The energy difference between axial and equatorial $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PH}_{3}$ (16a and 16b) is $2.7 \mathrm{kcal} \mathrm{mol}^{-1}$ with isomer 16a being more stable. Although the same trend is observed for the related $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PF}_{3}$ isomers ( $\mathbf{1 7 a}$ and $\mathbf{1 7 b}$ ), the energy difference is reduced to $1.0 \mathrm{kcal} \mathrm{mol}{ }^{-1}$. The $\mathrm{Fe}-\mathrm{PH}_{3}$ and $\mathrm{Fe}-\mathrm{PF}_{3}$ bond dissociation energies for the axial isomers are calculated to be 38.9 and $45.2 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. Interestingly, the $\mathrm{Fe}-\mathrm{PH}_{3}$ bond strength of 16a is somewhat lower than that for $\mathrm{Fe}-$ $\mathrm{NH}_{3}$ of 14a, which is opposite to the trend reported previously for a series of related complexes $\mathrm{M}(\mathrm{CO})_{5} \mathrm{XH}_{3}(\mathrm{M}=\mathrm{Cr}, \mathrm{Mo}, \mathrm{W}$ and $\mathrm{X}=\mathrm{N}, \mathrm{P}) .{ }^{96}$

16a

17a

16b

17b

Figure 3.2.12 Optimized geometries (B3LYP/II) of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{PH}_{3}\right)$ and $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{PF}_{3}\right)$, axial $(\mathbf{1 6 a}, \mathbf{1 7 a})$ and equatorial $(\mathbf{1 6 b}, \mathbf{1 7 b})$ isomers. Bond lengths are given in $\AA$, bond angles in degree.

For isomers 16a and 16b, the $\mathrm{Fe}-\mathrm{PH}_{3}$ bond lengths are calculated to be 2.272 $\AA$ and $2.243 \AA$, respectively. Thus, these bond distances are substantially longer than the corresponding $\mathrm{Fe}-\mathrm{PF}_{3}$ bond lengths of $2.156 \AA$ and $2.124 \AA$ found for 17 a and 17b. This is also reflected by the invariably higher bond dissociation energies of 45.2 and $44.1 \mathrm{kcal} \mathrm{mol}^{-1}$ calculated for the latter pair of isomers leading to a direct correlation of $\mathrm{Fe}-\mathrm{P}$ bond lengths and its bond strengths. It should be pointed out that Branchadell et al. found that this correlation is in general absent for a series of different phosphane iron tetracarbonyls. ${ }^{50,97}$

The CDA and NBO results classify both $\mathrm{PH}_{3}$ and $\mathrm{PF}_{3}$ to be better $\sigma$-donors than $\pi$-acceptors. Compared to analogous $\mathrm{NH}_{3}$ and $\mathrm{NF}_{3}$ complexes, the amount of $\sigma$ donation is higher for the phosphanes, and the extend of $\pi$-back donation is nonnegligible. With respect to the small energy differences of the axial and equatorial isomers of $\mathrm{PH}_{3}$ and $\mathrm{PF}_{3}$, respectively, the axial site-preference of these ligand is, however, less pronounced than for $\mathrm{NH}_{3}$ and $\mathrm{NF}_{3}$.

### 3.3.13 Ligand Site Preference in $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ Complexes

Figure 3.3 line up the ratios of $\sigma$-donation and $\pi$-back donation $\mathrm{d} / \mathrm{b}$ ( viz . $\mathrm{d} / \mathrm{b}$ from CDA and $\mathrm{q}(\sigma) \mathrm{L} / \mathrm{q}(\pi) \mathrm{L}$ from NBO analysis) for each ligand L according to its most stable isomer with the energy differences $\mathrm{E}_{\mathrm{rel}}$, calculated relative to the axial isomer of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$. Thus $\mathrm{d} / \mathrm{b} \geq 1$ indicates stronger $\sigma$-donating ligands, whereas $\mathrm{d} / \mathrm{b}$ $\leq 1$ represents stronger $\pi$-acceptors. Furthermore, $\mathrm{E}_{\text {rel }}<0$ shows that the equatorial isomer is more stable than the axial one, while $\mathrm{E}_{\text {rel }}>0$ indicates the opposite trend. Due to their nature as transition states, the axial ethylene (8a), acetylene (9a), vinylidene (10a), carbene (11a) and difluorcarbene (12a) iron tetracarbonyl complexes are omitted in this Figure. Only structures that were verified as local minima are considered in this comparison.

The first point revealed by the data shown in Figure 3.3 is that the relative donor-acceptor strengths $\mathrm{d} / \mathrm{b}$ predicted by the CDA and the NBO analysis are generally in good agreement with each other. Both partitioning schemes occasionally even give almost similar numerical values for the $\mathrm{d} / \mathrm{b}$ ratios. The general trend predicted with respect to the extend of $\sigma$-donation $/ \pi$-back donation supports the conventional classification of the ligand site preference in trigonal bipyramidal $\mathrm{d}^{8}$ complexes. ${ }^{45,46}$ Thus, a strong $\pi$-acceptor and poor $\sigma$ - donor like $\mathrm{NO}^{+}(\mathrm{d} / \mathrm{b}<0.5)$ prefers an equatorial coordination site, which is clearly shown by a large negative value of $\mathrm{E}_{\text {rel }}$. On the other hand, a strong $\sigma$-donor and poor $\pi$-acceptors like $\mathrm{NC}^{-}(\mathrm{d} / \mathrm{b}$ >> 1) only gives an energetically favourable structures if it is coordinated axially. This in turn leads to large positive value of $\mathrm{E}_{\text {rel }}$ (Figure 3.3a). This trend also holds for those ligands with smaller $\mathrm{d} / \mathrm{b}$ ratios ( $\mathrm{d} / \mathrm{b}>1$ ) and ligands like $\mathrm{CN}^{-}, \mathrm{NH}_{3}, \mathrm{NF}_{3} \mathrm{PH}_{3}$ and $\mathrm{PF}_{3}$, which still exhibit a distinct affinity for the coordination in axial position.

Figure 3.3 Plot of the calculated $\sigma$-donor $/ \pi$-acceptor ratio $\mathrm{d} / \mathrm{b}$ of the most stable isomers found for $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ and the energy difference $\mathrm{E}_{\text {rel }}=\mathrm{E}_{\text {equatorial }}-\mathrm{E}_{\text {axial }}$. Energies are in $\mathrm{kcal} \mathrm{mol}^{-1}$. (a) plot with respect to all ligands L covered in the text. (b) enlarged subsection showing those ligands with smaller $\mathrm{d} / \mathrm{b}$ ratios explicitly.

This is clearly shown by energy differences between their respective axial and equatorial isomers that are greater or equal than $1 \mathrm{kcal} \mathrm{mol}^{-1}$ (Figure 3.3b). Ligands with $\mathrm{d} / \mathrm{b}$ ratios close to unity, however, result in absolute values for $\mathrm{E}_{\text {rel }}$ of less than 1 kcal $\mathrm{mol}^{-1}$, indicating a somewhat indifferent ligand site preference. For the
complexes $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CS}$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~N}_{2}$ there is hardly any energy difference between their respective axial and equatorial isomers ( $\mathrm{E}_{\text {rel }} \approx 0$ ), which is consistent with the almost identical amounts of $\sigma$-donation and $\pi$-back donation predicted by the CDA method and the NBO analyses.

Note that amongst the various ligands considered in this study, only one noteworthy exception of the correlation between the $\mathrm{d} / \mathrm{b}$ ratios and the energy difference between axial and equatorial isomers is found. Only the complex involving molecular hydrogen reveals an inverse trend with regard to the ligand site preference. Thus, although the equatorial isomer of $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{H}_{2}\right)$ is more stable than its axial counterpart, its $\mathrm{d} / \mathrm{b}$ ratio indicates a more pronounced $\sigma$-donating character for $\mathrm{H}_{2}$. This however, might be due to an insufficiently large basis set used in the description of iron-coordinated molecular hydrogen. This point is under study with larger basis sets and different methods.

### 3.4 Summary

The theoretically predicted structural parameters of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ complexes obtained at the B3LYP/II level of theory are in very good agreement with available experimental results and previous theoretical estimates, as are the refined bond dissociation energies using the $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II} / \mathrm{B} 3 \mathrm{LYP} / \mathrm{II}$ combination of theoretical methods. The strongest $\mathrm{Fe}-\mathrm{L}$ bonds are found for the ligands $\mathrm{NO}^{+}, \mathrm{CN}^{-}, \mathrm{CH}_{2}$ and $\mathrm{CCH}_{2}$ with bond dissociation energies of $105.1,96.5,87.4$ and $83.8 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. For the corresponding complexes of $\mathrm{NC}^{-}, \mathrm{CF}_{2}$ and CS , these values decrease significantly to $78.6,64.3$ and $64.2 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. Even weaker bonds in the range of 45.2 to $37.3 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ are found for $\mathrm{CO}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}$, $\mathrm{NH}_{3}, \mathrm{PH}_{3}$ and $\mathrm{PF}_{3}$, while the bond dissociation energies of complexes involving $\mathrm{NF}_{3}$, $\mathrm{N}_{2}$ and $\eta^{2}-\mathrm{H}_{2}$ drop to less than $23.5 \mathrm{kcal} \mathrm{mol}^{-1}$.

Both charge partitioning schemes lead to almost identical results suggesting that strong $\pi$-accepting ligands like $\mathrm{NO}^{+}$prefer equatorial coordination sites of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ complexes, while strong $\sigma$-donor like $\mathrm{CN}^{-}$and $\mathrm{NC}^{-}$favor axial positions. This ligand site preference is found to be less pronounced as the ratio between the extend of $\sigma$-donation and $\pi$-back donation (d/b) approaches unity. However, ligands
with moderately large $\mathrm{d} / \mathrm{b}$ values like $\mathrm{NH}_{3}, \mathrm{NF}_{3}, \mathrm{PH}_{3}$, and $\mathrm{PF}_{3}$ still show a pronounced axial preference. Ligands like CS and $\mathrm{N}_{2}$, on the other hand, have almost equal charge contributions for $\sigma$-donation and $\pi$-back donation and consequently are thus characterized by an indifferent attitude with respect to the site preference in trigonal bipyramidal iron ( $\mathrm{d}^{8}$ ) complexes.

# Chapter 4. Carbene-, Carbyne-, and Carbon Complexes of Iron Possibility to Synthesize a Low-Valent Transition Metal Complex with a Neutral Carbon Atom as Terminal Ligand (CO) $\mathbf{4} \mathbf{F e C}$ 

### 4.1 Introduction

Transition metal (TM) alkyl compounds which have a $\mathrm{TM}_{-1} \mathrm{CR}_{3}$ single bond are already known since 1848, when Frankland accidentally synthesized diethylzinc while he attempted to prepare a free ethyl radical. ${ }^{2}$ Molecules with a $\mathrm{TM}=\mathrm{CR}_{2}$ double bond ${ }^{98,99}$ and $\mathrm{TM} \equiv \mathrm{CR}$ triple bond ${ }^{100,101}$ became much later isolated. TM carbene and carbyne complexes have been the focus of intensive experimental investigations since that time, because it was soon recognized that they are versatile compounds for organometallic synthesis. ${ }^{102}$ The bonding situation in molecules with transition metal-carbon multiple bonds attracted also the interest of theoreticians, who were intrigued by the finding that there are two classes of carbene and carbyne complexes which exhibit different chemical behavior. The different reactivity was explained with a bonding model which suggests different metal-carbene ${ }^{103}$ and metal-carbyne ${ }^{104}$ interactions in the two classes of compounds. It was proposed that one class of compounds have donor-acceptor metal-carbon bonds, while the other class has normal (shared-electron) covalent bonds where the metal and the carbon atom each contribute one electron to a two-electron bond. This is schematically shown in Scheme 4.1. Very recent $a b$ initio calculations proved that the bonding situations depicted in Scheme 4.1 are useful models for Fischer-type and Schrock-type carbene and carbyne complexes having donoracceptor bonds or shared-electron interactions, respectively. ${ }^{38 c}$ Because the metal-carbon bonds in Schrock-type compounds are not donor-acceptor bonds, they are better called alkylidenes and alkylidynes rather than carbene and carbyne complexes.

The next member in the series of metal-carbon bonds TM-CR 3, TM- $\mathrm{CR}_{2}, \mathrm{TM}-\mathrm{CR}$ is a bond with a terminal carbon atom TM-C. Transition metal carbide complexes are experimentally known, but all except one feature carbon atoms with at least two nearest neighbors. ${ }^{105}$ The only example of a TM complex with a terminal carbon atom is the anion $(\mathrm{NRAr})_{3} \mathrm{MoC}^{-}$which is isoelectronic to the nitride complex $(\mathrm{NRAr})_{3} \mathrm{MoN}\left(\mathrm{R}=\mathrm{C}\left(\mathrm{CD}_{3}\right)_{2} \mathrm{CH}_{3}\right.$, $\left.\mathrm{Ar}=\mathrm{C}_{6} \mathrm{H}_{3} \mathrm{Me}_{2}-3,5\right),{ }^{106}$ Scheme 4.1 shows also bonding models for a terminal TM-C

(a)

$\pi$ 1 $\approx=1^{-\mathrm{R}}$
(b)

(c)

Scheme 4.1 Schematic representation of the orbital interaction between a transition metal and (a) carbene ligand; (b) carbyne ligand; (c) carbon ligand. Donor-acceptor interactions are shown on top, shared-electron bonding is shown on the bottom.
donor-acceptor bond and a TM-C shared-electron bond which are similar to the orbital models of the carbene and carbyne complexes. A carbon atom in the excited ${ }^{1}$ D state (Scheme 4.2) has the same type of orbital interactions with a transition metal as a carbyne ligand (Scheme 4.1). An important difference is that the shared-electron TM-C bond leaves an unpaired electron at carbon which explains why most TM carbides have an unpaired electron at carbon atoms with more than one nearest neighbor. In contrast to the shared-electron bond has the TM-C donor-acceptor bond an electron lone-pair at the terminal carbon atom. The bonding situation in negatively charged (NRAr) $)_{3} \mathrm{MoC}^{-}$is analogous to $(\mathrm{NRAr})_{3} \mathrm{MoN}$, which has a shared-electron $\mathrm{Mo} \equiv \mathrm{N}$ triple bond and an electron lone pair. Thus, a complex with a transition metal-carbon donor-acceptor bond has not been synthesized so far. The carbon complex $(\mathrm{CO})_{4} \mathrm{FeC}$ has been suggested as a possible intermediate in the reaction of $(\mathrm{CO})_{4} \mathrm{FeCS}$ with $\mathrm{P}\left(\mathrm{NMe}_{2}\right)_{3}$. ${ }^{75 \mathrm{i}}$ It may be suggested that only compounds with a sharedelectron TM-C bond should be called TM carbides, while those with a donor-acceptor bond are better called TM carbon complexes. ${ }^{107}$

Scheme 4.2 Schematic representation of the electronic configuration of carbon in the ${ }^{1} D$ state with(right) and without(left) hybridization.

In this chapter, quantum chemical calculations of the model compound (CO) ${ }_{4} \mathrm{FeC}(\mathbf{1})$ which has a $\mathrm{Fe}-\mathrm{C}$ donor-acceptor bond are reported. The equilibrium geometry, $\mathrm{Fe}-\mathrm{C}$ bond dissociation energy ( BDE ) and the vibrational frequencies of $\mathbf{1}$ are calculated. The nature of the chemical bond was analyzed with the help of the NBO ${ }^{29}$ partitioning scheme and with the topological analysis of the electron density distribution. ${ }^{28}$ For comparison, the report about the bonding situation of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{CH}_{2}\right)(\mathbf{2}), \mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}(\mathrm{CH})(\mathbf{3})$ and $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{4})$ is also given. One has to be aware of the fact that $\mathbf{2}$ is not a good example for a stable Fischer-type carbene complex, because they can only become isolated when the carbene ligand has a $\pi$ donor substitute. ${ }^{102 a-d, \mathrm{i}}$ The model compound $\mathbf{3}$ is a good reference species, however, for the discussion of the bonding situation and stability of $\mathbf{1}$. The results of the calculations are used to predict the chemical properties of $\mathbf{1}$ and to discuss the possibilities to observe it experimentally. To this end $(\mathrm{CO})_{4} \mathrm{FeC}^{2}-\mathrm{BCl}_{3}(\mathbf{5})$ was also calculated, which is a complex of the Lewis base $\mathbf{1}$ with the Lewis acid $\mathrm{BCl}_{3}$.

### 4.2 Computational Methodology

The geometries have been optimized at the NL-DFT level using the three-parameter fit of the exchange-correlation potential suggested by Becke ${ }^{19}$ in conjunction with the LYP ${ }^{18}$ correlation potential (B3LYP). ${ }^{108}$ A small-core effective core potential (ECP) with a (441/2111/41) valence basis set for $\mathrm{Fe}^{27 \mathrm{c}}$, an ECP with a (31/31/1) valence basis set for $\mathrm{I}^{26 \mathrm{~b}}$ and $6-31 \mathrm{G}(\mathrm{d})$ basis sets ${ }^{53}$ for $\mathrm{C}, \mathrm{O}, \mathrm{H}$ have been employed in the geometry optimizations. This is the standard basis set II. ${ }^{55}$ The nature of the stationary points was examined by calculating the Hessian matrix. Improved energy calculations at the B3LYP/II optimized geometries have been carried out using coupled-cluster theory ${ }^{21}$ at the $\operatorname{CCSD}(\mathrm{T})$ level. ${ }^{109}$ The calculations have been performed with the program packages Gaussian $94 / 98^{56}$, ACES $\mathrm{II}^{57}$ and MOLPRO96/2000 ${ }^{58}$.

### 4.3 Geometries, Bond Energies and Vibrational Frequencies

Figure 4.1 shows the optimized geometries of $\mathbf{1 - 5}$ at B3LYP/II. The structures of $(\mathrm{CO})_{4} \mathrm{FeCH}_{2}$ (2) and $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{4})$ are shown previously in Fig 3.2.9 and 3.2.1 (Chapter 3), respectively. But for completeness, these structures are also included in Fig 4.1. This is also the case for $\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{6})$. The calculated energies are given in Table 4.1.
$(\mathrm{CO})_{4} \mathrm{FeC}(\mathbf{1 a})$ has a $\mathrm{C}_{3 \mathrm{v}}$ equilibrium geometry with an axial carbon ligand and a rather long $\mathrm{Fe}-\mathrm{CO}_{\text {trans }}$ bond. The isomeric form $\mathbf{1 b}$ which has the carbon ligand in the equatorial position is a transition state on the potential energy surface. $\mathbf{1 b}$ is calculated to be $7.7 \mathrm{kcal} / \mathrm{mol}$ higher in energy than $\mathbf{1 a}$ (Table 4.1 ). The $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C}$ bond in $\mathbf{1 a}$ is very short ( $1.614 \AA$ ). The $\mathrm{Fe}-\mathrm{CO}_{\text {trans }}$ bond of $\mathbf{1 a}(2.052 \AA)$ is much longer than the axial $\mathrm{Fe}-\mathrm{CO}$ bonds in $\mathrm{Fe}(\mathrm{CO})_{5}(4)(1.819 \AA)$. The short $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C}$ bond and the lengthening of the $\mathrm{Fe}-\mathrm{CO}_{\text {trans }}$ bond with respect to $\mathbf{4}$ indicate that the $\mathrm{Fe} \rightarrow \mathrm{C}_{\text {carbon }} \pi$-backdonation is quite strong which concomitantly weakens the $\mathrm{Fe} \rightarrow \mathrm{CO}_{\text {trans }}$ backdonation.

The bonding model for the donor-acceptor bonds shown in Scheme 4.1 suggests that there are two $\mathrm{Fe} \rightarrow \mathrm{C} \pi$ bonds in carbon complexes, while there is only one $\mathrm{Fe}-\mathrm{CR}_{2} \pi$ bond in carbene complexes. Figure 4.1 shows that the $\mathrm{Fe}-\mathrm{CH}_{2}$ bond in $\mathbf{2}$ is significantly longer than the $\mathrm{Fe}-\mathrm{C}$ bond in 1a. This holds for the isomer with the axial carbene ligand 2a and for the equatorial isomer $\mathbf{2 b}$. In contrast to the carbon complex $\mathbf{1}$ it is found that the equatorial form of the carbene complex $\mathbf{2 b}$ is a minimum on the potential energy surface, while the axial form $\mathbf{2 a}$ is a transition state which is $8.3 \mathrm{kcal} / \mathrm{mol}$ higher in energy than $\mathbf{2 b}$ (Table 4.1). A previous qualitative analysis of the orbital interactions between $\mathrm{Fe}(\mathrm{CO})_{4}$ and $\pi$ bearing ligands L led to the suggestion that $\pi$-acceptor ligands should prefer the equatorial position in (CO) $)_{4} \mathrm{FeL}$. ${ }^{46}$ This is in agreement with the calculated equilibrium structure of $\mathbf{2 b}$ and the experimental geometry of $(\mathrm{CO})_{4} \mathrm{Fe}\left(\mathrm{C}_{2} \mathrm{H}_{4}\right) .{ }^{85}$ The calculated energy minimum structure of $(\mathrm{CO})_{4} \mathrm{FeC}(\mathbf{1 a})$, however, defies the predicted preference of a $\pi$-acceptor ligand for an equatorial position. ${ }^{46}$ A possible explanation for this is given in the section about the bonding situation.

Figure 4.1 Optimized geometries (B3LYP/II) of 1-7. Distances in $\AA$, angles in degree.

Figure 4.1 shows also the calculated geometry of the carbyne complex $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}(\mathrm{CH})$ (3). The bonding model for the donor-acceptor bond of carbyne complexes $L_{n} T M-C R$ requires a somewhat arbitrary choice of charged fragments $L_{n} T M^{q}$ and $C R^{q}$, because the neutral fragments are open-shell species. Scheme 4.1 exhibits the most common choice of a positively charged carbyne ligand and a negatively charged metal fragment. A recent theoretical analysis of the bonding situation in carbyne complexes has shown that this model is a reasonable qualitative representation of the TM-CR bond. ${ }^{38 \mathrm{c}}$ Thus, the bonding situation in TM carbon and carbyne complexes should be quite similar. There are two metal-ligand $\pi$ bonds, but according to the model the $\pi$ backdonation in carbyne complexes should be stronger than in carbon complexes because the carbyne ligand CR has formally a positive charge. Figure 4.1 shows that $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}-\mathrm{CH}$ bond of $\mathbf{3}$ is indeed slightly shorter $(1.601 \AA)$ than the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C}$ bond of 1a. This lends some support to the bonding model for carbyne complexes (Scheme 4.1). It will be shown below, however, that the shorter $\mathrm{Fe}-\mathrm{CH}$ bond is better explained with the hybridization of the donor orbital of the CH ligand. It should be pointed out that the calculated bond lengths of $\mathrm{Fe}(\mathrm{CO})_{5}(4)$ are in excellent agreement with the most recent experimental value $\left(\mathrm{Fe}-\mathrm{CO}(\mathrm{ax})=1.811(2) \AA ; \mathrm{Fe}-\mathrm{CO}(\mathrm{eq})=1.803(2) \AA{ }_{\mathrm{A}}\right) .{ }^{63}$

The analysis of the bonding situation which is given below suggests that the carbon ligand of $\mathbf{1}$ should exhibit nucleophilic rather that electrophilic behavior, and that $\mathbf{1}$ can be classified as a Lewis base. The adduct of $\mathbf{1}$ with $\mathrm{BCl}_{3}$ is thus calculated. Figure 4.1 shows the equilibrium geometry of 5 which is a minimum on the potential energy surface. The B-C donor-acceptor bond of $\mathbf{5}$ is very short ( $1.587 \AA$ ). It is significantly shorter than the theoretically predicted donor-acceptor bond of the diaminocarbene complex with boron trichloride $\left(\mathrm{NH}_{2}\right)_{2} \mathrm{C}-\mathrm{BCl}_{3}\left(1.637 \AA\right.$ ) . ${ }^{110}$ The iron-carbon bond of $\mathbf{5}$ is clearly longer ( 1.654 $\AA$ ) than in the parent compound 1a, and the Fe-CO trans bond of $\mathbf{5}$ becomes much shorter ( 1.918 $\AA$ ) which indicate that the trans influence of the carbon ligand becomes weaker when it is bonded to a Lewis acid.

Figure 4.1 gives the geometries of $\mathrm{Fe}(\mathrm{CO})_{4}$ in the $\left({ }^{1} \mathrm{~A}_{1}\right)$ singlet $(\mathbf{6 S})$ and $\left({ }^{3} \mathrm{~B}_{2}\right)$ triplet (6T) states. The triplet form 6T is predicted at the B3LYP/II level to be $8.3 \mathrm{kcal} / \mathrm{mol}$ lower in energy than $\mathbf{6 S}$. This is in agreement with previous calculations. Li et al. ${ }^{71}$ calculated at the NL-DFT level a value of $1.7 \mathrm{kcal} / \mathrm{mol}$ in favor of the triplet state. Barnes et al. ${ }^{73}$ carried out MCPF calculations of 6S and 6T. They estimated that the triplet state of $\mathrm{Fe}(\mathrm{CO})_{4}$ should be
$15 \pm 5 \mathrm{kcal} / \mathrm{mol}$ below the singlet state. Thus, the calculated value of $8.3 \mathrm{kcal} / \mathrm{mol}$ seems to be reasonable. Unfortunately, the $\operatorname{CCSD}(\mathrm{T})$ calculation of 6 T did not converge. A triplet ground state of $\mathrm{Fe}(\mathrm{CO})_{4}$ has also been deduced from experimental studies by analysis of MCD measurements. ${ }^{60 \mathrm{~d}}$ The open-shell $\left({ }^{4} \Sigma\right)$ state $\mathbf{7 Q}$ of $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}$ is predicted at B3LYP/II to be $3.8 \mathrm{kcal} / \mathrm{mol}$ low in energy than the $\left({ }^{2} \Pi\right)$ state 7D.

${ }^{\text {a }}$ not converged

Table 4.2 gives the theoretically predicted bond dissociation energies $D_{e}$ and donoracceptor interaction energies $E_{\text {int }}$ of $\mathbf{1 - 5}$. The $D_{e}$ values and the ZPE corrected $D_{o}$ data of the iron-ligand bonds have been calculated for the dissociation of the Fe-L complexes yielding $\mathrm{Fe}(\mathrm{CO})_{4}$ or $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}$ and L in the electronic ground states. The interaction energies $\mathrm{E}_{\text {int }}$ have been calculated with respect to the lowest lying singlet states of the metal fragment and L which are relevant for the bonding models shown in Scheme 4.1. $\mathrm{E}_{\text {int }}$ value for the $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}-\mathrm{CH}$ bond of $\mathbf{3}$ is not given, because the dissociation of $\mathbf{3}$ into closed-shell fragments yields charged species. The associated dissociation energy thus involves a charge separation
reaction which should not be compared with the $E_{\text {int }}$ values of $\mathbf{1 a}, \mathbf{2 b}$ and $\mathbf{4}$. The $D_{e}$ and $E_{\text {int }}$ values of $\mathbf{5}$ are the same because the fragments of the bond dissociation reaction have singlet ground state.

Table 4.2 Calculated Bond Dissociation Energies $D_{e}{ }^{a}$ and Metal-Ligand Interaction Energies $\mathrm{E}_{\mathrm{int}}{ }^{\mathrm{b}}(\mathrm{kcal} / \mathrm{mol})$. ZPE Corrected Energies are Given in Parentheses.

${ }^{\text {a }}$ calculated with respect to the fragments in the electronic ground state
${ }^{\mathrm{b}}$ calculated with respect to the fragments in the lowest singlet state
${ }^{c}$ using the B3LYP/II value of the singlet-triplet energy difference for $\mathrm{Fe}(\mathrm{CO})_{4}(8.3 \mathrm{kcal} / \mathrm{mol})$
${ }^{\mathrm{d}}$ calculated using the experimental value for the ${ }^{3} \mathrm{P} \rightarrow{ }^{1} \mathrm{D}$ excitation energy for carbon ( $29.1 \mathrm{kcal} / \mathrm{mol}$ )
${ }^{\mathrm{e}}$ using the B3LYP/II optimized geometries

The theoretically predicted $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C}$ bond dissociation energy of $\mathbf{1 a}$ is very high. The calculated value at B3LYP/II is $\mathrm{D}_{\mathrm{e}}=84.1 \mathrm{kcal} / \mathrm{mol}$. The $\operatorname{CCSD}(\mathrm{T}) / I I$ value $94.5 \mathrm{kcal} / \mathrm{mol}$ is even higher. The $\operatorname{CCSD}(\mathrm{T}) / I I$ value for the bond energies of $\mathbf{1 - 5}$ are always higher than the B3LYP/II results but not very much. The carbon complex 1a has clearly the strongest metal-ligand bond of the investigated compounds. The carbyne complex 3 ( $\mathrm{D}_{\mathrm{e}}=76.4$ $\mathrm{kcal} / \mathrm{mol}$ at B3LYP/II) and the carbene complex 2b ( $\mathrm{D}_{\mathrm{e}}=72.5 \mathrm{kcal} / \mathrm{mol}$ at B3LYP/II; $\mathrm{D}_{\mathrm{e}}=$ $84.8 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T})$ ) also have strong $\mathrm{Fe}-\mathrm{L}$ bonds, while $\mathrm{Fe}(\mathrm{CO})_{5}(4)\left(\mathrm{D}_{\mathrm{e}}=33.6\right.$ $\mathrm{kcal} / \mathrm{mol}$ at $\mathrm{B} 3 \mathrm{LYP} / \mathrm{II} ; \mathrm{D}_{\mathrm{e}}=39.6 \mathrm{kcal} / \mathrm{mol}$ at $\left.\operatorname{CCSD}(\mathrm{T}) / \mathrm{II}\right)$ is clearly weaker bonded. The latter values may be compared with the experimental value for the first bond dissociation energy of $\mathrm{Fe}(\mathrm{CO})_{5}$ at $\left.0 \mathrm{~K} \mathrm{D}_{\mathrm{o}}=39 \pm 2 \mathrm{kcal} / \mathrm{mol}\right)$. ${ }^{74}$ However, this value refers to the dissociation of $\mathrm{Fe}(\mathrm{CO})_{5}$ yield the singlet state $\mathbf{6 S}$ of $\mathrm{Fe}(\mathrm{CO})_{4}$ and CO and thus, must be compared with the ZPE corrected $\mathrm{E}_{\text {int }}$ data given in Table 4.2. The theoretical values (39.0 $\mathrm{kcal} / \mathrm{mol}$ at $\mathrm{B} 3 \mathrm{LYP} / \mathrm{II} ; 45.1 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II})$ are in very good agreement with experiment.

The calculations predict that the order of the Fe-L bond dissociation energies $D_{e}$ has the trend $\mathrm{C}>\mathrm{CH}>\mathrm{CH}_{2} \gg \mathrm{CO}$. A comparison with the optimized geometries shows that the
$\mathrm{Fe}-\mathrm{L}$ bond energies clearly do not correlate with the bond lengths. The (CO) ${ }_{4} \mathrm{Fe}-\mathrm{CO}$ bond of $\mathbf{4}$ is shorter but significantly weaker than the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{CH}_{2}$ bond of $\mathbf{2 b}$, and the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C}$ of 1a is longer, but has a higher BDE than the $\mathrm{I}(\mathrm{CO})_{3} \mathrm{Fe}-\mathrm{CH}$ bond of $\mathbf{3}$. An explanation for the trend of the bond energies and for the bond length/bond energy correlation is given below in the section about bonding analysis (section 4.4).

The thermodynamic stabilization of the carbon ligand of $\mathbf{1 a}$ by the $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment was investigated. The latter moiety is isolobal to $\mathrm{CH}_{2}{ }^{111}$. Thus, ( CO$)_{4} \mathrm{FeC}$ may be compared with vinylidene $\mathrm{H}_{2} \mathrm{CC}$. The reaction energies of the hydrogenation of $\mathbf{1 a}$ and vinylidene were calculated as follows (reactions 4.1 and 4.2):

$$
\begin{align*}
& (\mathrm{CO})_{4} \mathrm{FeC}(\mathbf{1 a})+\mathrm{H}_{2} \rightarrow(\mathrm{CO})_{4} \mathrm{FeCH}_{2}  \tag{2b}\\
& \mathrm{H}_{2} \mathrm{CC} \quad+\quad \mathrm{H}_{2} \rightarrow \mathrm{H}_{2} \mathrm{CCH}_{2} \tag{4.1}
\end{align*}
$$

The reaction energy for reaction 4.1 is predicted at B3LYP/II to be $-69.3 \mathrm{kcal} / \mathrm{mol}$ $(-80.1 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II})$. The theoretically predicted energy for reaction 4.2 is -95.6 $\mathrm{kcal} / \mathrm{mol}(-107.5 \mathrm{kcal} / \mathrm{mol}$ at $\mathrm{CCSD}(\mathrm{T}) / \mathrm{II})$. Thus, the $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment stabilizes a carbon atom $26.3 \mathrm{kcal} / \mathrm{mol}(\mathrm{B} 3 \mathrm{LYP} / \mathrm{II} ; 27.0 \mathrm{kcal} / \mathrm{mol}$ at $\mathrm{CCSD}(\mathrm{T}) / \mathrm{II})$ more than methylene.

The interaction energies $\mathrm{E}_{\text {int }}$ involve the excitation energy of $\mathrm{Fe}(\mathrm{CO})_{4}$ from the triplet ground state to the singlet excited state and the triplet $\rightarrow$ singlet excitation energies of $C$ (in case of $\mathbf{1}$ ) and $\mathrm{CH}_{2}$ (in case of 2). The first excited singlet state of carbon which is relevant to the bonding model shown in Scheme 4.1 is the ${ }^{1} \mathrm{D}$ state, which can not accurately be calculated at the single-determinant level. ${ }^{112}$ The calculated energy of the ${ }^{3} \mathrm{P}$ ground state and the experimental value ( $29.1 \mathrm{kcal} / \mathrm{mol}$ ) ${ }^{113}$ for the ${ }^{3} \mathrm{P} \rightarrow{ }^{1} \mathrm{D}$ excitation energy are used in order to estimate $\mathrm{E}_{\text {int }}$ for $\mathbf{1 a}$. Table 4.2 shows that the $\mathrm{E}_{\text {int }}$ values discriminate the ligands $\mathrm{C}, \mathrm{CH}_{2}$ and CO even more than the $\mathrm{D}_{\mathrm{e}}$ data. $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C} \quad(\mathbf{1 a )}$ has a particularly large interaction energy which correlates well with the short bond.

The calculated BDE of the $(\mathrm{CO})_{4} \mathrm{FeC}-\mathrm{BCl}_{3}$ bond $\left(\mathrm{D}_{\mathrm{e}}=25.6 \mathrm{kcal} / \mathrm{mol}\right.$ at $\mathrm{B} 3 \mathrm{LYP} / \mathrm{II}$; $27.1 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II})$ is large enough to make 5 a possible target for synthetic work. ${ }^{118}$ It is interesting to compare the BDE of 5 with the calculated bond energy of the carbene complex $\left(\mathrm{NH}_{2}\right)_{2} \mathrm{C}-\mathrm{BCl}_{3}$ which is $\mathrm{D}_{\mathrm{e}}=59.7 \mathrm{kcal} / \mathrm{mol} .{ }^{110}$ Thus, the latter carbene complex has a much stronger yet $\mathrm{C}-\mathrm{BCl}_{3}$ bond than 5 . It will be shown below that this can
be explained with the hybridization at the carbon donor atom. The BDE of the $\mathrm{C}-\mathrm{BCl}_{3}$ bond of $\mathbf{5}$ is much higher, however, than the bond energy of $\mathrm{OC}-\mathrm{BCl}_{3}\left(\mathrm{D}_{\mathrm{e}}=2.3 \mathrm{kcal} / \mathrm{mol}\right) .{ }^{110}$ The rotation of the $\mathrm{BCl}_{3}$ ligand of $\mathbf{5}$ around the $\mathrm{Fe}-\mathrm{C}-\mathrm{B}$ axis is nearly unhindered. The rotational barrier is only $0.2 \mathrm{kcal} / \mathrm{mol}$ (B3LYP/II).

Table 4.3.1 Calculated Vibrational Frequencies $\left(\mathrm{cm}^{-1}\right)$ and IR Intensities $\left(\mathrm{km} \mathrm{mol}^{-1}\right)$ at B3LYP/II of (CO) ${ }_{4} \mathrm{FeC}(\mathrm{ax})$ and (CO) $)_{4} \mathrm{FeCBCl}_{3}$

Table 4.3 .1 shows the theoretically predicted vibrational spectra of $(\mathrm{CO})_{4} \mathrm{FeC}(\mathbf{1 a})$ and $(\mathrm{CO})_{4} \mathrm{FeC}-\mathrm{BCl}_{3}(\mathbf{5})$, which might help to identify the compound. The calculated wavenumbers and IR intensities of $\mathbf{2 - 4}$ are given in Table 4.3.2-4.3.4. The Fe-C stretching mode of 1a is predicted at $v=969 \mathrm{~cm}^{-1}$, but the IR intensity is very low. It could only be observed in the Raman spectrum. The Fe-C stretching mode in 5, which is coupled to the B-C fundamental is shifted to lower wavenumbers at $v=700 \mathrm{~cm}^{-1}$. It now has a high IR intensity and should help to identify the molecule. Also the B-C stretching mode at $v=1128 \mathrm{~cm}^{-1}$ might be useful for this purpose.

### 4.4 Analysis of the Bonding Situation

The NBO results shown in Table 4.4 are first discussed, which give insight into the Fe-L $\sigma$ and $\pi$ bonds of $\mathbf{1 a} \mathbf{- 5}$. The NBO method suggests for $\mathbf{1 a}$ a Lewis structure which has a $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C} \sigma$ and a degenerate $\pi$ bond. The $\sigma$ and $\pi$ bonds are strongly polarized towards the iron atom. This holds particularly for the degenerate $\pi$ bond, which has a weight of $81.5 \%$ at the iron side. The polarization of the $\mathrm{Fe}-\mathrm{C} \sigma$ bond of $\mathbf{1 a}$ is noteworthy, because it is the only one of the complexes $\mathbf{1 a} \mathbf{- 5}$ which has a larger amplitude on the iron side, while the other $\sigma$ bonds are more polarized towards carbon. This indicates that the carbon ligand is a strong donor in $\mathbf{1 a}$.

[^1]The carbon complex 1a possesses the strongest polarized Fe - L bonds of the complexes $\mathbf{1 a}-\mathbf{5}$. Another extreme value of $\mathbf{1 a}$ is the hybridization of the $\sigma$ bond at the carbon ligand. The NBO has mainly p character at carbon and only $14.4 \% \mathrm{~s}$ contribution. This is in strong contrast to the hybridization at the carbon atom of the CO ligand in $\mathrm{Fe}(\mathrm{CO})_{5}$, which has $63.7 \%$ s character in the $\mathrm{Fe}-\mathrm{CO}$ bond. The
hybridization at carbon is one reason why the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{CO}$ bond of $\mathbf{4}$ is comparatively short and yet significantly weaker than the Fe-L bonds of $\mathbf{1 a}-\mathbf{5}$. The high \%s character of the CO donor orbital means that it is rather compact and that the $\sigma$ orbital interactions take only place at shorter distances compared with donor orbitals which have more \%p character. Orbitals with higher \%s character are also energetically lower lying than those with more \%p character and thus, lead to weaker donor-acceptor interactions. However, the strength of the metal-ligand interactions is mainly determined by the $\mathrm{Fe} \rightarrow \mathrm{L} \pi$-backdonation. This will be discussed below.

Table 4.5 Calculated Charge Distribution Given by the NBO Analysis at B3LYP/II ${ }^{\text {a }}$

${ }^{\text {a }}$ Partial charge $q$, and population of the $\mathrm{p}(\pi) \mathrm{AO}$ of ligands.
${ }^{\mathrm{b}}$ Doubly degenerated orbital. The data give the occupation of a single orbital.
${ }^{\text {c }}$ Occupation of the $\pi$ orbital of CO.

Table 4.5 gives the charge distribution at the atoms and the orbital populations. The atomic partial charges indicate that the iron atom always carries a negative charge. The charge at Fe in $\mathbf{3}$ is smaller than in the other complexes. The ligand $\mathrm{C}, \mathrm{CH}$ and CO in 1a, $\mathbf{3}$ and $\mathbf{4}$ are positively charged and thus, are net charged donor ligands, while $\mathrm{CH}_{2}$ and $\mathrm{CBCl}_{3}$ in $\mathbf{2 b}$ and $\mathbf{5}$ are negatively charged (net acceptor ligands). It is noteworthy that the attachment of $\mathrm{BCl}_{3}$ in $\mathbf{5}$ reverses the net charge flow from the $\mathrm{Fe}(\mathrm{CO})_{4}$ metal fragment to the ligand. However, it should be pointed out that the total atomic charges are not a very useful probe for the interactions between the metal and the ligand, because they do not say anything about the topography of the charge distribution. A better probe for the charge distribution are the bond polarities shown in Table 4.4 and the orbital populations given in Table 4.5. The population of the $p(\pi)$ orbitals of the ligand atoms in the complex and in the free
ligand and the partial charges make it possible to estimate the amount of $\mathrm{Fe} \leftarrow \mathrm{L} \sigma$ donation and $\mathrm{Fe} \rightarrow \mathrm{L} \pi$-backdonation.

The results in Table 4.5 show that the carbon ligand is the strongest $\sigma$ donor and the strongest $\pi$ acceptor of the four ligands. This explains the very short and strong $\mathrm{Fe}-\mathrm{C}$ bond of $\mathbf{1 a}$. A surprising feature of $\mathbf{1 a}$ is that it is energetically lower lying than 1b. A qualitative discussion of the orbital interactions between a $\mathrm{X}_{4} \mathrm{TM}$ fragment and a ligand L in a trigonal bipyramidal complex $\mathrm{X}_{4}$ TML led to the suggestion that strong $\pi$ acceptor ligand tend to occupy the equatorial site. ${ }^{46}$ Yet, the strong $\pi$ accepting carbon ligand clearly prefers the axial position in $(\mathrm{CO})_{4} \mathrm{FeC}$. Thus, the preference for the axial position comes from the ( CO$)_{4} \mathrm{Fe}-\mathrm{C} \sigma$ interaction. Table 4.5 shows that the $\mathrm{Fe} \leftarrow \mathrm{C}$ donation is even larger than the $\mathrm{Fe} \rightarrow \mathrm{C}$ backdonation. The discussion about the orbital interactions in $\mathrm{X}_{4}$ TM-L considered only the $\pi$ orbitals of the L, but not the $\sigma$ orbitals. ${ }^{46}$ Strong $\sigma$ donor ligands such as $\mathrm{CN}^{-}$ occupied the axial position in $(\mathrm{CO})_{4} \mathrm{FeCN}^{-}$, which has been explained with the weak $\pi$ acceptor ability of the cyanide ligand. ${ }^{46}$ Therefore, the preference for the axial or equatorial site is not only determined by the $\pi$ orbital interactions, but also by the $\sigma$ orbitals. The latter effect is then responsible for the finding that $\mathbf{1 a}$ is energetically lower lying than 1b. The relative $\sigma$ donor/ $\pi$ acceptor strength explains also why the equatorial form of the carbene complex $\mathbf{2 b}$ is lower in energy than the axial form $\mathbf{2 a}$. Table 4.5 shows that the $\mathrm{CH}_{2}$ ligand is a stronger $\pi$ acceptor than $\sigma$ donor, while the carbon ligand is a stronger $\sigma$ donor than $\pi$ acceptor.

The carbyne complex $\mathbf{3}$ has a still shorter Fe-L bond than 1a, and the Wiberg bond index ${ }^{114}$ (Table 4.4) for the Fe-CH bond is higher (1.73) than for the Fe-C bond (1.55). However, the CH ligand has already one $\mathrm{p}(\pi)$ electron in the reference state of the neutral ligand, while carbon ( ${ }^{1} \mathrm{D}$ ) has none. The $\mathrm{Fe}-\mathrm{CH} \pi$ bonds of $\mathbf{3}$ are less polarized towards the iron end than the $\pi$ bonds of $\mathbf{1 a}$ (Table 4.4), but one of the four $\pi$ electrons of the former bonds comes from the ligand, while all four $\pi$ electrons of the $\mathrm{Fe}-\mathrm{C}$ bond of $\mathbf{1 a}$ come from Fe . Thus the neutral CH ligand is actually a weaker $\pi$ acceptor than C and $\mathrm{CH}_{2}$ (Table 4.5). The bonding situation of the neutral carbyne ligand in $\mathbf{3}$ is not directly comparable to the ligands in the carbon complex 1a and the carbene complex $\mathbf{2 b}$ because of the unpaired $\mathrm{p}(\pi)$ electron of $\mathbf{C H}$. The very
short $\mathrm{Fe}-\mathrm{C}$ bond of $\mathbf{3}$ is caused by the large $\%$ s character of the carbon $\sigma$ donor orbital (Table 4.4). The main conclusion from the NBO analysis is that the carbon ligand is a strong $\pi$ acceptor and an even stronger $\sigma$ donor.

The NBO results of $\mathbf{1}$ and $\mathbf{5}$ show that the $\mathrm{p}(\pi)$ population of the carbon ligand atom is enhanced by the complexation with $\mathrm{BCl}_{3}$. The population of the $\mathrm{p}(\pi) \mathrm{AOs}$ of carbon in $\mathbf{5}$ is 1.20 e ( 0.60 e in each orbital), which is a significantly higher value than in the parent complex $\mathbf{1 a}(0.94 \mathrm{e})$. Since the $\mathrm{BCl}_{3}$ moiety induces a charge flow from $\mathrm{Fe}(\mathrm{CO})_{4}$ to the $\mathrm{CBCl}_{3}$ ligand, it may be argued that there is a stronger $\mathrm{Fe} \rightarrow \mathrm{C} \pi$ backdonation in 5 than in 1a. However, a part of the carbon $p(\pi)$ population of 5 may also be due to hyperconjugation from the $\mathrm{BCl}_{3}$ ligand. The most important conclusion is, that the carbon ligand atom in $\mathbf{5}$ becomes electronically stabilized and sterically shielded by the $\mathrm{BCl}_{3}$ moiety.

The hybridization at the carbon donor atom of $\mathbf{5}$ explains why the $\mathrm{C}-\mathrm{BCl}_{3}$ bond is shorter yet weaker than the $\mathrm{C}-\mathrm{BCl}_{3}$ bond of $\left(\mathrm{NH}_{2}\right)_{2} \mathrm{C}-\mathrm{BCl}_{3}$. Table 4.4 shows that the bond orbital of the $\mathrm{C}-\mathrm{BCl}_{3}$ bond has $60.1 \%$ s and $39.9 \%$ p character at the carbon side, while it has a much higher p character in the carbene complex ( $25.5 \% \mathrm{~s}$, $74.3 \% \mathrm{p}$ ). ${ }^{110}$ The more diffuse and energetically higher lying p orbital induces stronger bonding at a larger distance. The $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{C} \sigma$ bond of $\mathbf{5}$ is now more polarized towards the carbon end, while in 1a it was more polarized towards Fe .

Topological analyses of the electron density distribution of $\mathbf{1 a}$ - $\mathbf{5}$ were carried out in order to seek further information about the electronic structure of molecules. Figure 4.2a shows the contour line diagram of the Laplacian distribution
${ }^{2} \rho(\mathbf{r})$ of $1 \mathbf{a}$ in the plane which contains the carbon ligand atom. The most important finding is the continuous area of charge concentration ( ${ }^{2} \rho(\mathbf{r})<0$, solid lines) which is found around the carbon ligand. This is in strong contrast to the shape of the Laplacian distribution of the carbene carbon atom of $\mathbf{2 b}$ which is displayed in Figure 4.2 b and 4.2c. The contour line diagram shown in Figure 4.2c exhibits the Laplacian distribution in the molecular plane which is perpendicular to the plane of the $\mathrm{CH}_{2}$ ligand. There is clearly a "hole" in the area of charge concentration, which is

Figure 4.2 Contour line diagrams of the Laplacian distribution $\nabla^{2} \rho(r)$ at B3LYP/II. Dashed lines indicate charge depletion $\left(\nabla^{2} \rho(\mathrm{r})>0\right)$; solid lines indicate charge concentration $\left(\nabla^{2} \rho(\mathrm{r})\right.$ $<0$ ). The solid lines connecting the atomic nuclei are the bond paths; solid lines separating the atomic nuclei indicate the zero-flux surfaces in the plane. The crossing points of the bond paths and zero-flux surfaces are the bond critical points $r_{b}$. The arrows in (c) show the hole in the valence sphere of the carbene ligand that is prone to attack by a nucleophilic agent.

[^2]indicated by the arrows. The charge depletion ( ${ }^{2} \rho(\mathbf{r})>0$, broken lines) at the carbene ligand of $\mathbf{2 b}$ is directed towards the in-plane $\mathrm{p}(\pi)$ orbital of the carbon atom. It shows the local electron deficiency at the carbene atom and it indicates the preferred direction for a nucleophilic attack.

The shape of the Laplacian distribution around the carbon ligand in 1a (Figure 4.2a) is similar to that of carbyne ligand in $\mathbf{3}$ (Figure 4.2d). The difference between the two ligands is that the carbon ligand of $\mathbf{1 a}$ has an area of charge concentration pointing away from the metal, while the CH ligand of $\mathbf{3}$ has a bonded hydrogen atom. The large area of charge concentration at the carbon ligand pointing away from Fe suggests a possibly nucleophilic behaviour of 1 a in chemical reactions. ${ }^{115}$ The nucleophilicity of $\mathbf{1 a}$ comes to the fore by the strong attraction of $\mathrm{BCl}_{3}$ moiety in 5. The Laplacian distribution of $\mathbf{5}$ is shown in Figure 4.2e. The shapes of the Laplacian distribution around the carbon atom of the $\mathrm{CBCl}_{3}$ ligand of $\mathbf{5}$ and the carbon atom of the CH ligand of $\mathbf{3}$ are very similar. Thus, the bond energy calculations, the topological analysis of the electron density distribution and the NBO calculations suggest that 5 might perhaps become isolated under appropriate conditions.

Table 4.6 gives the numerical results of the topological analysis of the electron density distribution. The data support the suggestion that the iron-carbon bonds of 1a and $\mathbf{5}$ have a significant covalent character. It has been shown that typical covalent bonds have large charge densities at the bond critical point $\rho_{\mathrm{b}}{ }^{116}$, and that the energy densities at the bond critical point $\mathrm{H}_{\mathrm{b}}$ is negative and large in magnitude. ${ }^{117}$ Table 4.6 shows that the $\mathrm{Fe}-\mathrm{C}$ bonds of $\mathbf{1 a}$ and $\mathbf{5}$ have strongly negative $\mathrm{H}_{\mathrm{b}}$ values and large positive $\rho_{\mathrm{b}}$ values.

### 4.5 Summary and Conclusion

The results of this chapter can be summarized as follows. The carbon complex $(\mathrm{CO})_{4} \mathrm{FeC}(\mathbf{1 a})$ is a minimum on the singlet potential energy surface. Structure 1a possesses an axial $\mathrm{Fe}-\mathrm{C}$ bond which has a theoretically predicted large dissociation energy $\mathrm{D}_{\mathrm{e}}=84.1 \mathrm{kcal} / \mathrm{mol}$ at B3LYP/II and $\mathrm{D}_{\mathrm{e}}=94.5 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / / \mathrm{II}$. The carbon ligand is a strong $\pi$-acceptor and an even stronger $\sigma$ donor. The analysis of
the electronic structure of 1a suggests that the carbon ligand atom should behave like a nucleophile. The donor-acceptor complex (CO) ${ }_{4} \mathrm{FeC}-\mathrm{BCl}_{3}(\mathbf{5})$ has a calculated C-B bond energy of $\mathrm{D}_{\mathrm{e}}=25.6 \mathrm{kcal} / \mathrm{mol}$ at B3LYP/II $\left(\mathrm{D}_{\mathrm{e}}=27.1 \mathrm{kcal} / \mathrm{mol}\right.$ at $\left.\operatorname{CCSD}(\mathrm{T}) / \mathrm{II}\right)$ and might become isolated under appropriate conditions.

# Chapter 5. The Relevance of Mono- and Dinuclear Iron Carbonyl Complexes to the Fixation and Stepwise Hydrogenation of $\mathbf{N}_{2}$ 

### 5.1 Introduction

The stepwise hydrogenation of dinitrogen to ammonia is one of the most important processes in biochemical research ${ }^{119}$ and of utmost interest to chemical industry. ${ }^{120}$ Beside the well understood heterogeneously catalyzed reduction following the Haber-Bosch process, ${ }^{121}$ deeper insight into the reduction of dinitrogen is necessary, particularly when dealing with biologically relevant systems. An example for this is the enzymatic fixation of $\mathrm{N}_{2}$ catalyzed by nitrogenases. ${ }^{122}$ Although the molecular structure of the Fe -Mo cofactor of a nitrogenase enzyme is well characterized by X-ray structure analysis, ${ }^{123}$ details of catalytically important features involved in the $\mathrm{N}_{2}$-reduction are, however, still not unequivocally answered. ${ }^{124}$ To this end, the binding site, the binding mode of $\mathrm{N}_{2}$ and the intermediates involved in the catalytic processes are still the source of much speculation. ${ }^{122,124}$ It is, however, widely accepted that the initial binding of dinitrogen occurs at the iron rather than the molybdenum centers. ${ }^{122}$ Theoretical studies based on different model systems of the Fe-Mo cofactor and various levels of theory are available. ${ }^{125}$ However, due to the complexity of the overall reduction process and the structure of the $\mathrm{Fe}-\mathrm{Mo}$ cofactor, a suitable model system for the Fe Mo nitrogenases that reasonably mimics its catalytic activity may be too large for a quantum chemical treatment at a reasonable level of theory. ${ }^{125}$ In addition to that, the nature of the actual intermediates of the enzymatic $\mathrm{N}_{2}$-fixation process still is a wide area of speculation. ${ }^{126}$ Although there are numerous results indicating that biological $\mathrm{N}_{2}$-fixation includes species of diazene and hydrazine, ${ }^{122}$ even the structure of the small four-atomic diazene in solution was discussed controversially for some time and only recently Sellmann and Hennige isolated trans $-\mathrm{N}_{2} \mathrm{H}_{2}$ by complexation out of solution. ${ }^{127}$

Due to the interest in the structure and reactivity of iron carbonyl complexes, ${ }^{128}$ the present study focuses on the influence and relevance of mono- and dinuclear iron carbonyl complexes of the general type $\left[\left\{\mathrm{Fe}(\mathrm{CO})_{4}\right\}_{\mathrm{n}} \mathrm{L}\right](\mathrm{n}=1$ for $\mathrm{L}=$
$\mathrm{NH}_{3}$ and $\mathrm{n}=1,2$ for $\mathrm{L}=\mathrm{N}_{2}, \mathrm{~N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}$ ) to the fixation and stepwise hydrogenation of $\mathrm{N}_{2}$. It should be emphasized that this approach is not intended to serve as a model study of the $\mathrm{Fe}-\mathrm{Mo}$ cofactor, but to gain a deeper insight to the reduction steps of $\mathrm{N}_{2}$ that are most affected by coordination to iron carbonyl fragments. ${ }^{124}$ Particular interest is thus drawn to thermodynamic changes between the "metalated" reaction in which the nitrogen-containing ligands are either coordinated by one or two iron tetracarbonyl fragments and the isolated, metal-free hydrogenation of $\mathrm{N}_{2}$. Moreover, the bonding situation of the $\mathrm{Fe}-\mathrm{L}\left(\mathrm{L}=\mathrm{N}_{2}, \mathrm{~N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}\right.$ and $\left.\mathrm{NH}_{3}\right)$ bond in terms of $\sigma$ donor $/ \pi$-acceptor abilities and the preferred coordination site of the ligands are addressed

### 5.2 Computational Details

Geometry optimizations are performed with Becke's three-parameter hybrid functional in combination with the correlation functional according to Lee, Yang and Parr (B3LYP). ${ }^{52}$ A small core pseudopotential and a (441/2111/41) split-valence basis set according to Hay and Wadt are used for iron, ${ }^{27 c}$ whereas an all-electron 6$31 \mathrm{G}(\mathrm{d})$ basis set is chosen for the main group elements. ${ }^{109}$ It was shown previously that this combination of basis sets (further abbreviated as basis set II) in combination with the aforementioned functional predicts equilibrium geometries of transition metal complexes reasonably well. ${ }^{55}$ All structures discussed in this paper are verified to represent local minima on their potential energy surfaces by harmonic frequency calculations at the same level of theory. Refined estimates of relative energies are obtained by single-point calculations of the B3LYP/II geometries using both the B3LYP functional and coupled-cluster theory with singles, doubles and pertubative estimates of triple substitution $(\operatorname{CCSD}(\mathrm{T})){ }^{21} \operatorname{CCSD}(\mathrm{~T})$ and basis set II are used for estimating relative energies between isomeric forms of diazene, hydrazine and all iron carbonyl complexes. Refined reaction enthalpies $\Delta H_{R}^{0} \quad(T=0 K)$ for the individual hydrogenation reactions, however, are predicted using basis sets that consists out of the aforementioned basis set for the metal and the elements C and O , but are extended by either the $6-31 G(d, p)$ and the $6-311+G(d, p)$ basis sets for $N$ and H. These combinations of basis sets are further abbreviated as $\{I I \& 6-31 \mathrm{G}(\mathrm{d}, \mathrm{p})\}$ and $\{$ II \& 6-311+G(d,p) \}, respectively.

The $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ values obtained for the hydrogenation steps of the metal-free reactions are compared with their analogous steps involving mononuclear iron carbonyl fragments. The resulting $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}$ values indicate whether $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ of an individual reduction step decreases $\left(\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}<0\right)$ or increases $\left(\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}>0\right)$ on going from the reactions of the isolated to the coordinated species. The corresponding $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}$ values obtained for the individual reduction steps involving mono- and dinuclear iron carbonyl fragments are used likewise. Unless otherwise noted, relative enthalpies obtained at the $\operatorname{CCSD}(\mathrm{T}) /\{$ II \& $6-311+\mathrm{G}(\mathrm{d}, \mathrm{p})\} / / \mathrm{B} 3 \mathrm{LYP} / \mathrm{II}$ level of theory are the basis for the comparison between the metal-free hydrogenation steps of $\mathrm{N}_{2}$ and the reactions following the reduction of $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}$. With respect to the large resources needed for a proper description of the reactions involving dinuclear species, the comparisons between the hydrogenation steps involving mono and dinuclear iron carbonyl complexes are based on the B3LYP/\{II \& 6-311+G(d,p)\}//B3LYP/II energies only. For the evaluation of the reaction enthalpies only the most stable isomers within a reaction sequence are considered.

Reaction enthalpies and relative energies are corrected by zero-point vibrational energy (ZPE) contributions obtained at the B3LYP/II level of theory. The nature of the $\mathrm{Fe}-\mathrm{N}$ and $\mathrm{N}-\mathrm{N}$ bonds is examined using the natural bond orbital $(\mathrm{NBO})^{29}$ partitioning scheme and the charge decomposition analysis (CDA). ${ }^{33}$ All calculations use the program packages Gaussian94/98, ${ }^{56}$ MOLPRO96/2000, ${ }^{58}$ and CDA2.1. ${ }^{59}$

### 5.3 Results and Discussion

### 5.3.1 Stepwise Hydrogenation of Isolated Dinitrogen

Calculated geometries and structural parameters of dinitrogen 1, diazene 2a and 2b, hydrazine 3a-3c and ammonia $\mathbf{4}$ are shown in Figure 5.1. Reaction enthalpies obtained using a variety of energy evaluations based on the B3LYP/II geometries are summarized in Table 5.2. Details of the levels of theory necessary for a reasonable treatment of the stepwise hydrogenation of isolated dinitrogen to
ammonia have been reported in a previous paper and the reaction enthalpies provided by this study serve as reference values for the present work. ${ }^{129}$ Thus, for the individual hydrogenation steps shown in Equations (1) - (3) the benchmarks for the reaction enthalpies $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ are $49.2 \mathrm{kcal} \mathrm{mol}^{-1}$ (1), $-23.1 \mathrm{kcal} \mathrm{mol}^{-1}$ (2) and -44.7 kcal mol $^{-1}(3) .{ }^{129}$

$$
\begin{array}{llll}
\mathrm{N}_{2}+\mathrm{H}_{2} & \rightarrow & \mathrm{~N}_{2} \mathrm{H}_{2} \\
\mathrm{~N}_{2} \mathrm{H}_{2}+ & \mathrm{H}_{2} & \rightarrow & \mathrm{~N}_{2} \mathrm{H}_{4} \\
\mathrm{~N}_{2} \mathrm{H}_{4}+ & \mathrm{H}_{2} & \rightarrow & 2 \mathrm{NH}_{3} \tag{3}
\end{array}
$$

The data summarized in Table 5.1 clearly show that for all three hydrogenation steps convergence of the results is achieved when basis sets of at least $6-311+G(d, p)$ quality are used. At our highest level of theory, the enthalpies of reaction are $51.4 \mathrm{kcal} \mathrm{mol}^{-1}$ for (1), $-19.3 \mathrm{kcal} \mathrm{mol}^{-1}$ for (2) and $-43.3 \mathrm{kcal} \mathrm{mol}^{-1}$ for (3), respectively, which is in good agreement with the aforementioned reference data. ${ }^{129}$ We note, however, that the predicted $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ for the second reduction step (2) is $3.8 \mathrm{kcal} \mathrm{mol}^{-1}$ too high, while the reaction enthalpies of reactions (1) and (3) are off by 2.2 and $1.4 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. A more economic, yet reasonably accurate alternative is given by $\operatorname{CCSD}(\mathrm{T})$ energy evaluations in combination with the $6-311+G(d, p)$ basis set. The deviations from the reference values are then between 4.8 and $1.2 \mathrm{kcal} \mathrm{mol}^{-1}$, i.e. the $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ values are $51.9 \mathrm{kcal} \mathrm{mol}^{-1}$ for (1), -18.3 kcal $\mathrm{mol}^{-1}$ for (2) and $-43.5 \mathrm{kcal} \mathrm{mol}^{-1}$ for (3). For larger molecules, for which $\operatorname{CCSD}(\mathrm{T})$ is no longer affordable, B3LYP/\{II \& 6-311+G(d,p)\} single-point energies are recommended. This approach leads to deviations from the reference that are particular small for reaction (2) and (3). The calculated $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ values of 45.3 kcal $\mathrm{mol}^{-1}$ for (1), $-22.4 \mathrm{kcal} \mathrm{mol}^{-1}$ for (2) and $-44.1 \mathrm{kcal} \mathrm{mol}^{-1}$ for (3) thus show that this approach offers a very economic way to reliable hydrogenation enthalpies.

Figure 5.1 Optimized geometries of $\mathrm{N}_{2}(\mathbf{1}), \mathrm{N}_{2} \mathrm{H}_{2}(\mathbf{2}), \mathrm{N}_{2} \mathrm{H}_{4}$ (3) and $\mathrm{NH}_{3}$ (4). Experimental values are given in italics. All bond lengths are in $\AA$. The symmetry used for the geometry optimization is given in parentheses, while relative energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) with respect to the most stable isomers are given in square brackets. Angles are omitted for clarity.

Table 5.1 Hydrogenation enthalpies $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ (in $\mathrm{kcal} \mathrm{mol}^{-1}$ ) for the stepwise reduction of isolated dinitrogen.

${ }^{a}$ Ref 129.

The calculated $\mathrm{N}-\mathrm{N}$ bond lengths of $\mathbf{1}$ is $1.105 \AA$, whereas the analogue bond length of $\mathbf{2 a}$ and $\mathbf{2 b}$ are calculated to be 1.246 and $1.241 \AA$ Á, respectively. Compared to corresponding experimental data, the differences are quite small and in the range of 0.001 to $0.007 \AA \AA^{130,131}$ The same also holds for the $\mathrm{N}-\mathrm{H}$ bond length of $\mathrm{NH}_{3}$ (4), that is, a small deviation from the experimental data by $0.007 \AA \dot{\AA}$ is found. ${ }^{132}$ Relatively large deviations from the experiment are, however, found for the structural parameters of $\mathbf{3 a} \mathbf{- 3} \mathbf{3}$. The experimental $\mathrm{N}-\mathrm{N}$ bond length of $1.449 \AA \AA$ is larger than the one in the most stable hydrazine isomer $\mathbf{3 a}$ by $0.014 \AA \AA^{132}$ The calculated value is, however, in perfect agreement with other high-level ab initio estimates, ${ }^{129}$ implying that a re-examination of the experimental $\mathrm{N}-\mathrm{N}$ bond length might be worthwhile. The calculated bond angles of 2, 3 and $\mathbf{4}$ are generally in good agreement with the available literature data and no significant deviations are found.

At the standard level of theory, viz. $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II} /$ /B3LYP/II the trans-isomer of diazene 2a is predicted to be more stable than the $c i s$-isomer 2b by $5.5 \mathrm{kcal} \mathrm{mol}^{-1}$, which is in line with previous results. ${ }^{129,133}$ Furthermore, the calculations predict the gauche isomer 3a to be the most stable form of hydrazine, which is consistent with other data. ${ }^{133}$ The energy difference to the corresponding trans-isomer $\mathbf{3 b}$ is, however, very small and only $0.3 \mathrm{kcal} \mathrm{mol}^{-1}$, whereas the analog cis-hydrazine $\mathbf{3 c}$ is significantly less stable than 3a by $8.1 \mathrm{kcal} \mathrm{mol}^{-1}$.

### 5.3.2 Stepwise Hydrogenation in the Presence of Mononuclear Iron Carbonyl Complexes

The influence of mononuclear iron carbonyl complexes to the stepwise hydrogenation of coordinated $\mathrm{N}_{2}$ is evaluated by comparing the individual reduction steps shown in Equations (4) - (6) with their metal-free analogues (1) - (3).

| $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}$ | + | $\mathrm{H}_{2}$ | $\rightarrow$ | $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}$ |
| :--- | :--- | :--- | :--- | :--- |
| $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}$ | + | $\mathrm{H}_{2}$ | $\rightarrow$ | $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}$ |
| $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}$ | + | $\mathrm{H}_{2}$ | $\rightarrow$ | $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{NH}_{3}+\mathrm{NH}_{3}$ |

Optimized geometries of the iron carbonyl complexes and the relative energies between the respective axial and equatorial isomers are shown in Figure 5.2. Table 5.2 summarizes the hydrogenation enthalpies $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ for reactions (4) - (6) obtained at various levels of theory. Table 5.3 lists the calculated bond dissociation energies $\mathrm{D}_{0}$ between the $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment and the nitrogen-containing ligands together with the NBO and CDA data.

Figure 5.2 Optimized geometries of the complexes $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \quad(\mathbf{5}),(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2} \quad(\mathbf{6})$, $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}(7)$, and $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{NH}_{3}(\mathbf{8})$. All bond lengths are in $\AA$ and the symmetry used for the geometry optimisation is given in parentheses. Relative energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) with respect to the most stable isomers are given in square brackets. Angles and $\mathrm{N}-\mathrm{H}$ bond lengths are omitted for clarity.

Figure 5.2 (Continued)

The most intriguing effect of the $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment on the stepwise hydrogenation of coordinated $\mathrm{N}_{2}$ is that the enthalpy of hydrogenation of 35.8 kcal $\mathrm{mol}^{-1}$ for the first reduction step (4) is significantly lower by $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}=-16.1 \mathrm{kcal}$ $\mathrm{mol}^{-1}$ compared to the analogue step of isolated $\mathrm{N}_{2}(1)$. One can not observe similarly drastic effect for the second and third reduction steps. To this end, the reduction of $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}(5)$ is almost as exothermic as the corresponding hydrogenation (2) of
isolated $\mathrm{N}_{2} \mathrm{H}_{2}\left(\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}=-0.2 \mathrm{kcal} \mathrm{mol}^{-1}\right)$. For the hydrogenation of $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}$ (6), an even less exothermic behavior than for the metal-free analogue (3) is found and $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}$ is calculated to be $4.00 \mathrm{kcal} \mathrm{mol}^{-1}$.

Table 5.2 Hydrogenation enthalpies $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ (in $\mathrm{kcal} \mathrm{mol}^{-1}$ ) for the stepwise reduction of (CO) ${ }_{4} \mathrm{Fe}-\mathrm{N}_{2}$. ${ }^{\text {a }}$

${ }^{\mathrm{b}}$ Total charge of the $\mathrm{Fe}(\mathrm{CO})_{4}$ complex fragment.
$\mathbf{1}$ is both a weak $\sigma$-donor and $\pi$-acceptor ligand. The small energy difference between the two possible isomers $\mathbf{5 a}$ and $\mathbf{5 b}$ of the complex $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}$, in which $\mathrm{N}_{2}$ is either coordinated axially or equatorially, implies no pronounced coordination site preference. ${ }^{134}$ The structures of $\mathbf{5 a}$ and $\mathbf{5 b}$ show $\mathrm{Fe}-\mathrm{N}_{2}$ bond lengths of $1.912 \AA$ and $1.907 \AA$, respectively. This is in contrasts to the results of Radius et al., ${ }^{47}$ who
predicted the $\mathrm{Fe}-\mathrm{N}_{2}$ bond length of axial $\mathrm{N}_{2}$ to be shorter than that of equatorial $\mathrm{N}_{2}$. The energy difference of $0.5 \mathrm{kcal} \mathrm{mol}^{-1}$ between $\mathbf{5 a}$ and $\mathbf{5 b}$ is in favour of the axial isomer, which again contrast the results of the aforementioned group. ${ }^{47}$ Note, however that the chosen level of theory is surely beyond chemical accuracy ( $\leq 1.0$ $\mathrm{kcal} \mathrm{mol}{ }^{-1}$ ) and therefore the small energy difference is not conclusive. Interestingly, however, the discrepancy of the calculated relative energy between $\mathbf{5 a}$ and $\mathbf{5 b}$ also has it's pendant in experimental chemistry. On the one hand, the reaction of $\mathrm{Fe}(\mathrm{CO})_{5}$ with $\mathrm{N}_{2}$ in polyethylene film implies that $\mathrm{N}_{2}$ may occupy an equatorial rather an axial coordination site, ${ }^{79}$ whereas photolysis experiments of $\mathrm{Fe}(\mathrm{CO})_{5}$ in nitrogencontaining matrices ${ }^{60 \mathrm{a}}$ show an opposite behaviour, that is a more stable axial than equatorial isomer. The $\mathrm{N}-\mathrm{N}$ distances of isomers $\mathbf{5 a}$ and $\mathbf{5 b}$ are both slightly longer than in isolated dinitrogen 1. The elongation on coordination is in the range of 0.006 to $0.010 \AA$ indicating that the $\mathrm{N}-\mathrm{N}$ triple bond only experiences a weak "activation". In addition, the calculated $\mathrm{Fe}-\mathrm{N}$ bond energy of $22.9 \mathrm{kcal} \mathrm{mol}^{-1}$ also implies a relatively weak interaction between $\mathrm{N}_{2}$ and the $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment.

The diazene complex formed by the first hydrogenation step (4) shows a somewhat different behavior compared to the analogue dinitrogen complex. First, the energy difference of $5.4 \mathrm{kcal} / \mathrm{mol}^{-1}$ between the axial $\mathbf{6 a}$ and equatorial $\mathbf{6 b}$ isomers is indeed significant and in favour of the axial isomer. Second, this preference towards axial coordination is also mirrored by the $\sigma$-donor $/ \pi$-acceptor abilities of diazene. ${ }^{134}$ NBO as well as CDA data both imply that $\mathrm{N}_{2} \mathrm{H}_{2}$ is at least as worse as $\pi$-acceptor as $\mathrm{N}_{2}$, but at the same time a slightly better $\sigma$-donor (Table 5.3). Finally, the $\mathrm{Fe}-\mathrm{N}$ bond dissociation energy of $\mathbf{6 a}$ is calculated to be $39.3 \mathrm{kcal} \mathrm{mol}^{-1}$, which is considerably higher than the corresponding value calculated for 5a. The much stronger bond in $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}$ than that in $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}$ is the reason why the first hydrogenation step of $\mathrm{N}_{2}$ becomes energetically more favored by the $\mathrm{Fe}(\mathrm{CO})_{4}$ complexation. Structural changes of diazene on complexation are again very small and the $\mathrm{N}-\mathrm{N}$ bond is lengthened by only $0.003 \AA$.

Further hydrogenation of coordinated $\mathrm{N}_{2} \mathrm{H}_{2}$ leads to the corresponding hydrazine complex (5). NBO and CDA suggest that hydrazine is a significantly stronger $\sigma$-donor than diazene or dinitrogen (Table 5.3). Axial coordination of $\mathrm{N}_{2} \mathrm{H}_{4}$ should therefore be predominant, which is supported by the large energy difference of
$6.4 \mathrm{kcal} \mathrm{mol}^{1}$ that favors the axial isomer $7 \mathbf{a}$ over its equatorial pendant $7 \mathbf{b}$. Interestingly, the former more stable isomer has hydrazine coordinated as trans $-\mathrm{N}_{2} \mathrm{H}_{4}$, which is not the most stable conformation for the isolated case. At the same time, the less stable equatorial isomer has $\mathrm{N}_{2} \mathrm{H}_{4}$ coordinated in its most stable gauche conformation. Structural changes of $\mathrm{N}_{2} \mathrm{H}_{4}$ on coordination are significant as shown by the lengthening of the $\mathrm{N}-\mathrm{N}$ bond in $7 \mathbf{7 a}$ of $0.033 \AA$ í with respect to isolated $\mathrm{N}_{2} \mathrm{H}_{4}$. This relatively strong influence on the internal structure of $\mathrm{N}_{2} \mathrm{H}_{4}$ is also mirrored by the large $\mathrm{Fe}-\mathrm{N}$ bond dissociation energy of $42.8 \mathrm{kcal} \mathrm{mol}^{-1}$, which is in fact the highest $\mathrm{D}_{0}$-value encountered in this study. Note, that at the same time the calculated $\mathrm{Fe}-\mathrm{N}$ bond length of $\mathbf{7 a}$ of $2.078 \AA$ is significantly larger than the corresponding bond lengths found in complexes 5 and $\mathbf{6}$, which exhibit weaker bonds between iron and the nitrogen containing ligands.

In the final step (6) of the overall reduction process, coordinated hydrazine is reduced to ammonia. The $\mathrm{NH}_{3}$ ligand is found by CDA and NBO to be an equally strong $\sigma$-donor as $\mathrm{N}_{2} \mathrm{H}_{4}$, whereas its $\pi$-acceptor capability is close to zero (Table 5.3). Again a dominant preference of the axial $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}$ isomer $8 \mathbf{~ a}$ over the equatorial isomer by $6.0 \mathrm{kcal} \mathrm{mol}^{-1}$ is found, which is in line with crystallographic data and IR spectra. ${ }^{93}$ The estimate for the $\mathrm{Fe}-\mathrm{N}$ bond dissociation energy is $38.9 \mathrm{kcal} \mathrm{mol}^{-1}$ and the calculated $\mathrm{Fe}-\mathrm{N}$ bond length is $2.098 \AA \dot{\AA}$. Both values show slight deviations from those found for the analogous hydrazine complex 7a. These differences are, however, small thus indicating a close resemblance of these two complexes.

### 5.3.3 Stepwise Hydrogenation in the Presence of Dinuclear Iron Carbonyl Complexes

Figure 5.3 shows the optimized geometries of the dinuclear complexes $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}-\mathrm{Fe}(\mathrm{CO})_{4} \quad$ (9), $\quad(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}-\mathrm{Fe}(\mathrm{CO})_{4} \quad$ (10) and $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}-\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{1 1})$, considered in the hydrogenation steps according to equations (7) - (9). Tables 5.3 and 5.4 summarize the hydrogenation enthalpies for the individual steps and the bond dissociation energies as well as the NBO/CDA data, respectively.

Figure 5.3 Optimized geometries of the dinuclear iron tetracarbonyl complexes $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}-\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{9}),(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}-\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{1 0})$, and $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}-\mathrm{Fe}(\mathrm{CO})_{4}$ (11). All bond lengths are in $\AA$. The symmetry used for the geometry optimization is given in parentheses.

Table 5.4 Hydrogenation enthalpies $\Delta \mathrm{H}_{\mathrm{R}}^{0}$ (in $\mathrm{kcal} \mathrm{mol}^{-1}$ ) for the stepwise reduction of $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}-\mathrm{Fe}(\mathrm{CO})_{4} .^{\text {a }}$

The coordination of dinitrogen by two iron tetracarbonyl fragments results in a further significant decrease of the hydrogenation enthalpy of the first reduction step (7) by $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}=-13.1 \mathrm{kcal} \mathrm{mol}^{-1}$ compared to the analogue step (4) involving only one $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment. ${ }^{135}$ The overall decrease of the hydrogenation enthalpy with respect to the metal free reaction (1) thus becomes $27.1 \mathrm{kcal} \mathrm{mol}^{-1} .{ }^{135}$ This considerable change of the thermochemistry is so much more interesting as it affects the first reduction step only. To this end, the second (8) and third (9) hydrogenation
steps are even less exothermic than their mononuclear analogues (5) and (6). The $\Delta \Delta \mathrm{H}_{\mathrm{R}}^{0}$ values calculated on going from (5) to (8) and from (6) to (9) are 4.0 and 1.1 kcal $\mathrm{mol}^{-1}$, respectively.

The $\mathrm{Fe}(\mathrm{CO})_{4}$ fragments in 9 are twisted against each other by $8.7^{\circ}$. The rotation barrier is extremely low and one can find several different isomers that are energetically not distinguishable from each other. In comparison to the mononuclear analogue 5a further significant alterations of structural parameters can not be observed. Note that the $\mathrm{Fe}-\mathrm{N}$ bond length becomes shorter by 0.007 A , which is paralleled by the lengthening of the $\mathrm{N}-\mathrm{N}$ bond by $0.008 \AA$. The CDA and NBO data in Table 5.5 show that the $\sigma$-donor properties of $\mathrm{N}_{2}$ embraced by two iron tetracarbonyl fragments is hardly changed compared to $\mathbf{5 a}$ and only the $\pi$-acceptor characteristics are somewhat enhanced. The overall $\mathrm{Fe}-\mathrm{N}_{2}-\mathrm{Fe}$ bond dissociation energy is calculated to be $32.5 \mathrm{kcal} \mathrm{mol}^{-1}$, which translates to a $\mathrm{Fe}-\mathrm{N}$ bond dissociation energy per $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment of $16.0 \mathrm{kcal} \mathrm{mol}^{-1}$. Comparison of these data with the bond dissociation energy obtained for $\mathbf{5 a}$ implies a decreased bond strength between an individual $\mathrm{Fe}(\mathrm{CO})_{4}$ subunit and $\mathrm{N}_{2}$.

Further hydrogenation of 9 results in the formation of the corresponding diazene complex $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{2}-\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{1 0})$. The $\mathrm{Fe}-\mathrm{N}$ as well as the $\mathrm{N}-\mathrm{N}$ bond lengths of $\mathbf{1 0}$ are calculated to be $1.948 \AA$ And $1.265 \AA ́$, respectively. These values are in good agreement with the structural data of the related $\left[\mu-\mathrm{N}_{2} \mathrm{H}_{2}\left\{\mathrm{Fe}\left(\mathrm{PPr}_{3}\right)\left(\mathrm{S}_{4}{ }^{\prime}\right)\right\}_{2}\right]$ ( $\mathrm{S}_{4}{ }^{12-}=1,2$-bis(2-mercaptophenylthio) ethane(2-)) complex reported by Sellmann and co-workers. ${ }^{136}$ The small deviations of less than $0.052 \AA$ are noteworthy as such $\mathrm{Fe}(\mathrm{II})\left(\mathrm{S}_{4}{ }^{\prime}\right.$ ) complexes involving multidentate organosulfur ligands are often used as model compounds for the $\mathrm{Fe}-\mathrm{Mo}-, \mathrm{Fe}-\mathrm{V}$ - and $\mathrm{Fe}-\mathrm{Fe}-$ nitrogenases. ${ }^{122,124,136}$ A nonnegligible shortening of the $\mathrm{Fe}-\mathrm{N}$ bond by $0.011 \AA$ and a lengthening of the $\mathrm{N}-\mathrm{N}$ bond by $0.016 \AA \AA$ on going from 6a to its dinuclear pendant $\mathbf{1 0}$ should be noted. Interestingly, CDA and NBO data indicate that the ability of diazene to act as $\sigma$ donor is almost unaltered. Only a slight increase of the $\pi$-acceptor capabilities of $\mathrm{N}_{2} \mathrm{H}_{2}$ is observed. The $\mathrm{Fe}-\mathrm{N}$ bond dissociation energy of $\mathbf{1 0}$ follows the same trend as shown above for the corresponding dinitrogen complex. That is, the bond strength per $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment is smaller when compared to the mononuclear case, whereas
the overall binding energy obtained by complexation with two $\mathrm{Fe}(\mathrm{CO})_{4}$ fragments is significantly larger.

In the second step of the overall reduction process (8), the analogue hydrazine complex $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}-\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{1 1})$ is formed by hydrogenation of coordinated diazene. The comparison with complex 7a shows hardly any shortening of the $\mathrm{Fe}-\mathrm{L}$ bond length or lengthening of the $\mathrm{N}-\mathrm{N}$ bond. It should be pointed out that the NBO data imply that both the $\sigma$-donor as well as the $\pi$-acceptor abilities of $\mathrm{N}_{2} \mathrm{H}_{4}$ decrease slightly on going from the mononuclear complex to $\mathbf{1 1}$. With respect to the $\sigma$-donor character this is also supported by the corresponding CDA values. Although the analogue $\pi$-acceptor value implies a stronger $\pi$-backdonation of $\mathrm{N}_{2} \mathrm{H}_{4}$ in the dinuclear complex 11, the predicted magnitude is too small to account for a significant $\pi$ acceptor character of $\mathrm{N}_{2} \mathrm{H}_{4}$.

### 5.4 Conclusion

Density functional and $a b$ initio calculations were used to evaluate the influence of iron tetracarbonyl complexes to the stepwise hydrogenation of dinitrogen. In comparison to the metal-free reduction process, it is found that complexation by one or two $\mathrm{Fe}(\mathrm{CO})_{4}$ fragments results in a pronounced change of the thermochemistry of the first hydrogenation step, namely the reduction of coordinated $\mathrm{N}_{2}$ to $\mathrm{N}_{2} \mathrm{H}_{2}$. The effects on the second and third hydrogenation steps, viz the hydrogenation of coordinated $\mathrm{N}_{2} \mathrm{H}_{2}$ and $\mathrm{N}_{2} \mathrm{H}_{4}$ are much weaker and even less exothermic reduction processes compared with the metal-free hydrogenation are predicted. The decrease of the hydrogenation enthalpy is larger for the reduction of the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2}-\mathrm{Fe}(\mathrm{CO})_{4}$ than it is for the reduction of $(\mathrm{CO}) \mathrm{Fe}-\mathrm{N}_{2}$. Furthermore, NBO and CDA data imply a consistent trend of the $\sigma$-donor $/ \pi$-acceptor behavior of the nitrogen-containing ligands that correlates with the relative energies between the respective isomers. Thus, ligands with comparatively high $\sigma$-donor capabilities like $\mathrm{N}_{2} \mathrm{H}_{4}$ and $\mathrm{NH}_{3}$ give iron tetracarbonyl complexes in which the axial isomers are considerably more stable than their equatorial pendant. In addition to that, only ligands like $\mathrm{N}_{2}$ and $\mathrm{N}_{2} \mathrm{H}_{2}$, which show noticeable $\pi$-acceptor quantities in their respective $\mathrm{Fe}(\mathrm{CO})_{4}$ complexes, are affected by the formation of dinuclear complexes.

Thus, their $\mathrm{Fe}-\mathrm{N}$ bond lengths are shorter and the $\mathrm{N}-\mathrm{N}$ bonds are longer in the dinuclear complexes than in their mononuclear analogues. This behavior is also mirrored by a slight increase of the $\pi$-acceptor ability on going from (CO) ${ }_{4} \mathrm{Fe}-\mathrm{X}$ to $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{X}-\mathrm{Fe}(\mathrm{CO})_{4}\left(\mathrm{X}=\mathrm{N}_{2}, \mathrm{~N}_{2} \mathrm{H}_{2}\right)$ complexes. Such structural changes are absent for $\mathrm{N}_{2} \mathrm{H}_{4}$, and both its $\sigma$-donor as well as its $\pi$-acceptor behavior are less pronounced in $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}-\mathrm{Fe}(\mathrm{CO})_{4}$ than in $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{N}_{2} \mathrm{H}_{4}$.

# Chapter 6. $\quad{ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR Chemical Shifts of the Iron Carbene Complex (CO) $\mathbf{4 F C F}_{2}$ — A Theoretical Study at Non-Local DFT (BP86 and B3LYP) Level 

### 6.1 Introduction

Metal carbene complexes have remarkable importance as intermediates of many organometallic reactions ${ }^{98,137-138}$ such as olefin metathesis ${ }^{139}$ catalytic reduction of CO by $\mathrm{H}_{2}{ }^{140}$, Ziegler-Natta polymerization reaction, ${ }^{141}$ etc. What drew the attention of the theoreticians soon after the report of the first stable TM carbene complex $1964{ }^{98}$ is the nature of the chemical bond between a transition metal (TM) and a carbene fragment $\mathrm{CR}_{2}$. The most successful bonding model explains the difference between Fischer and Schrock carbene complexes by using the singlet and triplet states of the $\mathrm{CR}_{2}$ fragments and the residual as building blocks for the respective complexes (Scheme 4.1 (a) in Chapter 4).

Fischer-type complexes ${ }^{102}$ are characterized by electrophilic reactivity of the carbene ligand. The TM-carbene bond in this type of complexes is described in terms of donor-acceptor interactions between a ( ${ }^{1} \mathrm{~A}_{1}$ ) singlet carbene and a singlet metal fragment with $\mathrm{R}_{2} \mathrm{C} \rightarrow \mathrm{TM} \sigma$-donation and $\pi$-back donation $\mathrm{R}_{2} \mathrm{C} \leftarrow \mathrm{TM}$. The TM-C bond in Schrock complexes ${ }^{142}$ is described as a covalent bond between a $\left({ }^{3} \mathrm{~B}_{1}\right)$ triplet carbene and a triplet metal fragment. Generally, stable Fischer complexes have a $\pi$ donor group such as $\mathrm{OR}, \mathrm{NR}_{2}$ or halogens at the carbene ligand which is bound to a TM in a low oxidation state, while Schrock-type complexes have nucleophilic carbene ligands typically with hydrogen, alkyl or aryl groups but no $\pi$-donor substituents at the carbene carbon atom. Although many TM carbene complexes can easily be identified to belong to one of the two classes, some species are difficult to classify. For example, dihalocarbenes have singlet ground state and large singlet $\rightarrow$ triplet excitation energy ${ }^{143}$ and thus donor-acceptor bonding should be exclusively formed in their respective TM complexes, i.e. they are typical Fischer complexes. However, they may in fact exhibit either nucleophilic or electrophilic behaviour at the carbene center indicating no strict separation between these two classes. ${ }^{144}$

In the past decades, a lot of experimental techniques have been applied to characterize carbene complexes. NMR spectroscopy is the most important analytical method for monitoring and controlling the success of the syntheses and providing the first indications to which class of compounds the molecule belongs. NMR data often give detailed information about the electronic structure of the products.

However, because of the high activity of carbene complexes, it is often difficult to isolate the monomer, determine the structure parameters and characterize the nature of the complex. Iron tetracarbonyl complex with fluorine substituted carbene ligand may be a good example for illustrating this case. ${ }^{145}$ As all attempts to directly observe and designate NMR spectroscopy were unsuccessful, theoretical calculations maybe helpful to predict the electronic structure.

It is now possible to calculate heavy-atom molecules like TM compounds reliably by using either classical quantum chemical methods in conjunction with pseudopotentials ${ }^{55}$ or density functional theory (DFT). ${ }^{146}$ Though DFT methods for calculating NMR chemical shifts are still young, some standards have already been established. The excellent performance of DFT methods in predicting NMR parameters for TM compounds was reviewed recently. ${ }^{147}$ Here, calculated NMR results of the model complex (CO) $)_{4} \mathrm{FeCF}_{2}$ at the non-local DFT (BP86 and B3LYP) level are reported. To my best knowledge, it is the first report of fully optimized geometry of the iron carbene complex at the DFT (BP86) level. The electronic structure of the complex was analyzed within the framework of natural bond orbital analysis (NBO). ${ }^{29}$ The nature of donor-acceptor bonding was examined by charge decomposition analysis (CDA). ${ }^{33}$ The gauge-invariant atomic orbitals (GIAO) ${ }^{148}$ were used to calculate chemical shifts of relevant compounds for its varieties of advantages ${ }^{149}$ over the individual gauge for localized orbitals (IGLO) ${ }^{150}$, although there is no definite statement about the accuracy of these two methods. ${ }^{147}$

However, as the accurity of the theoretically predicted NMR chemical shift for this kind of carbene complexes is unknown, it is ambiguous to say the calculated NMR values are reliable. Any way, the ${ }^{13} \mathrm{C}$ chemical shifts of the parent compound $\mathrm{Fe}(\mathrm{CO})_{5}$ have been experimentally obtained, and the theoretical NMR values of
$\mathrm{Fe}(\mathrm{CO})_{5}$, such as chemical shifts, magnetic susceptibility, and spin-spin coupling constants are available. ${ }^{151}$ A comparison between experimental and theoretical works could be done, at least for $\mathrm{Fe}(\mathrm{CO})_{5}$, and the extension from $\mathrm{Fe}(\mathrm{CO})_{5}$ to $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CF}_{2}$ should be reliable for ${ }^{13} \mathrm{C}$ NMR calculations at the same theoretical level. As for ${ }^{19} \mathrm{~F}$ NMR data, some previous theoretical works make it possible to compare them with the results reported here.

### 6.2 Methods

Geometries of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ and related complexes $\mathrm{Fe}(\mathrm{CO})_{5}$ and $\mathrm{Fe}(\mathrm{CO})_{4}$ were optimized at the BP86 ${ }^{15,17}$ level of theory with the help of Gaussian 94/98 ${ }^{56}$ suite of $a b$ initio programs. Vibrational analyses were done numerically at the same level. $\operatorname{CCSD}(\mathrm{T})^{21}$ calculations were carried out with Molpro96/200058 using the BP86optimized geometries. In $\operatorname{CCSD}(\mathrm{T})$ calculations, triple excitations were taken into consideration noniteratively and core orbitals were excluded from the active space.

Three kinds of basis set systems (denoted as BS-A, BS-B, and BS-C) were used in the work. The standard basis II $^{55}$ (here denoted as BS-A) was employed for geometry optimization and for following frequency calculations, which has smallcore effective potential (ECP) with a (441/2111/41) valence for $\mathrm{Fe}^{27 \mathrm{c}}$ and $6-31 \mathrm{G}(\mathrm{d})^{53}$ basis for other atoms. In BS-B, the core electrons of Fe were replaced with a Stuttgart $\mathrm{ECP}^{26 \mathrm{a}}$ with a more flexible ( $311111 / 2111 / 411$ ) basis set. D95 ${ }^{152}$ basis sets were used for $\mathrm{C}, \mathrm{H}, \mathrm{Cl}, \mathrm{F}$. In BS-C, the same basis set and ECPs as those in BS-B were used for iron. For other atoms, the Bochum basis set $\mathrm{II}^{153}$ was employed. No corrections were introduced concerning the use of ECPs in the NMR chemical shift calculation of this work.
${ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR chemical shifts were calculated using GIAO ${ }^{148}$ approach with the help of Gaussian 94/98 ${ }^{56}$. CDA calculations have been performed using the program CDA 2.1. ${ }^{59}$

### 6.3 Results and Discussion

### 6.3.1 Geometries, Vibrational Frequencies and Bond Dissociation Energies

Figure 6.1 Optimized geometries (BP86/BS-A) of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}(\mathbf{1})$, $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{2})$, and $\mathrm{Fe}(\mathrm{CO})_{4}(\mathbf{3})$. Distances in $\AA$, angles in degree.

The optimized geometries of the carbene complex $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ ( $\mathbf{1}$ ), the relevant parent complex $\mathrm{Fe}(\mathrm{CO})_{5}(\mathbf{2})$ and the dissociation fragment $\mathrm{Fe}(\mathrm{CO})_{4}$ (3) are
shown in Figure 6.1. Both the total energies and the relative energies calculated at the BP86/BS-A and $\operatorname{CCSD}(\mathrm{T}) / \mathrm{BS}-\mathrm{A}$ levels are presented in Table 6.1. The $\mathrm{CF}_{2}$ ligand may occupy either an axial or equatorial position in a trigonal bipyramidal iron complex. The only isomer of $\mathbf{1}$ is the equatorial one in $\mathrm{C}_{2 \mathrm{v}}$ symmetry ( $\mathbf{1 b}$ ). The axial form where the ligand $\mathrm{CF}_{2}$ is clipsed to one equatorial CO is a transition state. Further optimization could not locate another stationary point where the ligand $\mathrm{CF}_{2}$ accepts a staggered form respective to one of the equatorial CO group. Therefore, it is reasonable that $\mathbf{1 a}$ is $2.2 \mathrm{kcal} / \mathrm{mol}$ at the BP86/BS-A level and $4.2 \mathrm{kcal} / \mathrm{mol}$ at the $\operatorname{CCSD}(\mathrm{T}) / \mathrm{BS}-\mathrm{A}$ level less stable than $\mathbf{1 b}$, which means that the potential energy surface of $\mathbf{1}$ is very flat.

Table 6.1 Calculated total energies $\mathrm{E}_{\text {tot }}$ (au.), relative energies $\mathrm{E}_{\text {rel }}(\mathrm{kcal} / \mathrm{mol})$, zero point vibrational energies ZPE ( $\mathrm{kcal} / \mathrm{mol}$ ), number of imaginary frequencies $i$, theoretically predicted bond dissociation energy $D_{e}$ and $D_{o}(\mathrm{kcal} / \mathrm{mol})^{\mathrm{a}, \mathrm{b}, \mathrm{c}}$ at BP86/BS-A and at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{BS}-\mathrm{A}$.

${ }^{\text {a }}$ using BP86/BS-A optimized geometries
${ }^{\mathrm{b}}$ using ZPE values at BP86/BS-A
${ }^{c}$ with respect to singlet $\mathrm{Fe}(\mathrm{CO})_{4}$ and $\mathrm{CF}_{2}$ or CO
${ }^{\mathrm{d}}$ BP86 total energies are omitted for clarity
${ }^{\text {e }}$ SCF not converged

A previous theoretical study ${ }^{154}$ using the SCF-MO method showed that the barrier to rotation around the $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ is very low, only $2.9 \mathrm{kcal} / \mathrm{mol}$ for $(\mathrm{CO})_{4} \mathrm{FeCH}(\mathrm{OH})$. What should be noted is that an assumed geometry was used in the work. By using a fully optimized geometry of $\mathbf{1 b}$, this work can give a more reliable answer about the barrier to rotation of the carbene ligand group in the iron carbene complex.

Unfortunately, the stationary point which is symmetry equivalent $\left(\mathrm{C}_{2 \mathrm{v}}\right)$ to $\mathbf{1 b}$ could not be located by means of optimization and other standard methods for finding a transition state. By varying only the rotational angle $90^{\circ}$ around the $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ bond an unstable isomer $\mathbf{1 c}$ is obtained, which is $14.1 \mathrm{kcal} / \mathrm{mol}$ higher in energy than $\mathbf{1 b}$ (Scheme 6.1). Further optimization led to a second order saddle point 1d which corresponds to simultaneous (1) rotation around the $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ axis and (2) changes of the axial and equatorial $(\mathrm{OC}) \mathrm{Fe}(\mathrm{CO})$ angle. 1d is $10.3 \mathrm{kcal} / \mathrm{mol}$ at the BP86/BS-A level less stable than $\mathbf{1 b}$. Therefore, it can be concluded that the barrier to rotation should be lower than $14.1 \mathrm{kcal} / \mathrm{mol}$.

Scheme 6.1 Schematic representation of the rotation barrier of $\mathrm{CF}_{2}$ group around $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ axis for $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ (eq) complex. Barrier height is obtained at BP86/BS-A approximately (see text fro detail)

The calculated $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ dissociation energy with respect to singlet $\mathrm{Fe}(\mathrm{CO})_{4}$ (3a) is $\mathrm{D}_{0}=60.1 \mathrm{kcal} / \mathrm{mol}$ at $\mathrm{BP} 86 / \mathrm{BS}-\mathrm{A}$ and $\mathrm{D}_{0}=63.8 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{BS}-\mathrm{A}$
(both using ZPE-correction at the BP86/BS-A level), respectively, which is about 14$19 \mathrm{kcal} / \mathrm{mol}$ stronger than that of $\mathrm{Fe}-\mathrm{C}$ in its parent complex $\mathrm{Fe}(\mathrm{CO})_{5}$ (2) (Table 6.1) for which the $\mathrm{D}_{\mathrm{o}}$ value at the $\operatorname{CCD}(\mathrm{T}) / \mathrm{BS}-\mathrm{A}$ level is comparable with experimental data. ${ }^{74}$ It is reasonable to deduce that $\mathrm{D}_{\mathrm{o}}$ is slightly overestimated ( $\sim 3 \mathrm{kcal} / \mathrm{mol}$ ) for the carbene complex 1b at the highest theoretical level of the work, $\operatorname{CCSD}(\mathrm{T})$. The energy difference between singlet ( $\mathbf{3 a}$ ) and triplet iron tetracarbonyl ( $\mathbf{3 b}$ ) is negligible as it is only $0.2 \mathrm{kcal} / \mathrm{mol}$ at the BP86/A level.

The geometry of the fragment $\mathrm{Fe}(\mathrm{CO})_{4}$ in the complex is more similar to singlet 3a than to triplet $\mathbf{3 b}$. The geometries of the free ligand $\mathrm{CF}_{2}$ is calculated to be $1.330 \AA$ for the C-F bond length and $104.0^{\circ}$ for the F-C-F angle. These values are in good agreement with experimental results of $1.3 \AA / 104.8^{\circ}{ }^{152}$ or $1.3035 \AA$ $/ 104.8^{\circ}{ }^{156}$. The calculated geometry of the $\mathrm{CF}_{2}$ group changes only little ( $0.009 \AA$ and $0.9^{\circ}$ ) on going from the free ligand to complex $\mathbf{1 b}$. Hence, $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}(\mathbf{1 b})$ may be explained as a combination of singlets $\mathrm{Fe}(\mathrm{CO})_{4}$ and $\mathrm{CF}_{2}$.

There are no experimental results available to make a direct comparison of the Fe-carbene distance with the theoretical value. One can compare the calculated value of $\mathbf{1 b}$ with the complex $(\mathrm{CO})_{4} \mathrm{Fe}=\mathrm{C}=\mathrm{C}=\mathrm{C}\left[\mathrm{C}(\mathrm{tBu})_{2} \mathrm{OC}(\mathrm{O}) \mathrm{O}\right],{ }^{87 \mathrm{~b}}$ where the ligand is equatorial. A rather short bond distance ( $1.80 \AA$ ) was observed in experiment. The calculated $\mathrm{Fe}-\mathrm{C}$ bond length of $\mathbf{1 b}$ is $1.827 \AA$.

Table 6.2 lists the calculated vibrational frequencies and IR intensities of $\mathbf{1 b}$, which may help to characterize the possible monomer complex experimentally.

Table 6.2 Calculated vibrational frequencies $\left(\mathrm{cm}^{-1}\right)$ and IR intensity $\left(\mathrm{km} \mathrm{mole}^{-1}\right)$ of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}(\mathrm{eq})$ at BP86/II level

Figure 6.2 Schematic representation of the most important Kohn-Sham (KS) orbitals of the free ligand and the carbene complex $\mathbf{1 b}$ for $\mathrm{F}_{2} \mathrm{C}$ $\mathrm{Fe}(\mathrm{CO})_{4}$ interactions as revealed by CDA. LUMO(a) and $\mathrm{HOMO}(\mathrm{b})$ of free carbene (left) and donation-back donation interaction of $\mathbf{1 b}$ (right). d $\approx 0, \mathrm{~b}=0.232, \mathrm{r}=-0.046$ for KSO 48 and $\mathrm{d}=0.178, \mathrm{~b}=0.018, \mathrm{r}=-0.003$ for KSO 44.

The CDA results at BP86/A show that the complex $\mathbf{1 b}$ can be reasonably interpreted as a complex between the closed-shell fragments $\mathrm{Fe}(\mathrm{CO})_{4}$ and $\mathrm{CF}_{2}$ since the residue term is $\approx 0$. The CDA data for $\mathbf{1 b}$ indicate also that the carbene ligand $\mathrm{CF}_{2}$ is a stronger electron donor $(d=0.544)$ than acceptor $(b=0.291)$ which is similar to the situation in carbene complexes of group 6. ${ }^{37,38 c}$ The most important Kohn-Sham (KS) orbitals of the free ligand $\mathrm{CF}_{2}$ and the carbene complex $\mathbf{1 b}$ are schematically shown in Figure 6.2. The HOMO (Figure 6.2, b) is antibonding in character while the LUMO (Figure 6.2, a) is strongly antibonding for the free ligand. These orbitals interact with those of $\mathrm{Fe}(\mathrm{CO})_{4}$ fragment of the same symmetry.

A previous study (see chapter 2) using the NBO partitioning scheme at the B3LYP/BS-A level predicted that the donation $\mathrm{F}_{2} \mathrm{C} \rightarrow \mathrm{Fe}(\mathrm{CO})_{4}$ and the back donation $\mathrm{F}_{2} \mathrm{C} \leftarrow \mathrm{Fe}(\mathrm{CO})_{4}$ are almost the same amount and the back donation is slightly stronger (0.01e) than the donation which correlates well with the ligand equatorial site preference. Here the distinction in energy between 1a and 1b at the BP86/A level is even subtle. Consequently, the ligand $\mathrm{CF}_{2}$ should have even weaker site preference to coordinate equatorially. More interesting, the NBO results obtained at the BP86 level show that the $\mathrm{CF}_{2}$ ligand is a somewhat stronger donor than acceptor, which indicates a weak dependence of NBO values on the computational method.

### 6.3.3 ${ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR Chemical Shifts

Table 6.3 Calculated ${ }^{13} \mathrm{C}$ NMR and ${ }^{19} \mathrm{~F}$ NMR chemical shifts of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}(\mathrm{eq})$ and $\mathrm{Fe}(\mathrm{CO})_{5}$ at the DFT (BP86, B3LYP) level (in ppm). ${ }^{\text {a, b, }}$,

${ }^{\mathrm{e} 1}(\mathrm{CO})_{4} \mathrm{Fe}=\mathrm{C}=\mathrm{C}=\mathrm{C}(\mathrm{tBu})_{2}(\mathbf{1})$ in $\mathrm{CDCl}_{3},-50^{\circ} \mathrm{C}$
${ }^{\mathrm{e} 4}(\mathrm{CO})_{4} \mathrm{Fe}=\mathrm{C}=\mathrm{C}=\mathrm{C}\left[\mathrm{C}(\mathrm{tBu})_{2} \mathrm{OC}(\mathrm{O}) \mathrm{O}\right](4)$ in $\mathrm{CDCl}_{3}, 0^{\circ} \mathrm{C}$.
${ }^{\mathrm{f}}$ see Mann, B. E. J. Chem. Soc., D, 1971, 1173.

The calculated ${ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR chemical shifts of $\mathbf{1 b}$ are given in Table 6.3. The relevant data of $\mathbf{2}$ are also collected for comparison.

Due to the dynamical rearrangement of the axial and equatorial carbonyl groups only one signal is recorded for $\mathbf{2}$ in ${ }^{13} \mathrm{C}$ NMR experiment. The calculated GIAO values (average of axial and equatorial ones) at the DFT level with the biggest
basis set (BS-C) are ~ 20 (BP86//BP86/BS-A) and 35 (B3LYP//BP86/BS-A) ppm higher than the experimental value ${ }^{157}$ (Table 6.3). Similar results were obtained in Simion and Sorensen's quantum mechanical study ${ }^{151 a}$. The computational error in this work is acceptable because of the moderate basis set. By enlarging the basis set on going from BS-A to BS-C, the calculated GIAO-NMR values converge well. With 2 as a reference (assigned to 210 ppm ), the estimated ${ }^{13} \mathrm{C}$ NMR values of $\mathbf{1 b}$ with BS-C are given in parentheses (Table 6.3), which is in better agreement with experiment. The chemical shift of the carbonyl carbon is predicted to be at 208.9 (BP86) and 210.5 (B3LYP) ppm. Most iron complexes with a formal $\mathrm{Fe}=\mathrm{C}$ bond have low-field ${ }^{13} \mathrm{C}$ resonance ${ }^{158}$. For complex $\left[(\mathrm{MeO})_{3} \mathrm{P}\right]_{2}(\mathrm{CO})_{2} \mathrm{Fe}=\mathrm{C}=\mathrm{CHCHO}$, in which the two trimethyl phosphite ligands were axial, even lower field ${ }^{13} \mathrm{C}$ resonances (above 300 ppm ) than the values given in Table 6.3 were reported. ${ }^{159}$ Note that, the experimental values of carbene compounds cited in Table 6.3 (column 8) have different ligands.

Table 6.4 Calculated DFT-GIAO Anisotropies of ${ }^{13} \mathrm{C}$ Chemical Shifts for Carbenic Carbon Atom in $(\mathrm{CO})_{4} \mathrm{Fe}^{-} \mathrm{CF}_{2}(\mathbf{1 b})$. ${ }^{\text {a, }}$ b

| Method | Basis set | $\delta(\mathrm{YY})$ | $\delta(\mathrm{XX})$ | $\delta(\mathrm{ZZ})$ | $\Delta(\mathrm{YY}-\mathrm{XX})$ | $\Delta(\mathrm{XX}-\mathrm{ZZ})$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| BP86 | BS-A | 436.1 | 171.5 | 126.7 | 264.6 | 44.8 |
|  | BS-B | 476.6 | 185.6 | 132.0 | 291.0 | 53.5 |
|  | BS-C | 485.6 | 190.0 | 138.3 | 295.6 | 51.7 |
| B3LYP | BS-A | 489.5 | 170.9 | 123.3 | 318.6 | 47.6 |
|  | BS-B | 540.6 | 186.8 | 132.0 | 353.7 | 54.9 |
|  | BS-C | 546.6 | 190.2 | 134.1 | 356.4 | 56.1 |

[^3]Final investigation was made by examining the calculated anisotropies of ${ }^{13} \mathrm{C}$ chemical shifts of carbenic C in $\mathbf{1 b}$. Table 6.4 shows that the component of the ${ }^{13} \mathrm{C}$ chemical shift tensor, which is parallel to the Fe-C carbene bond of the complex $\mathbf{1 b}(\mathrm{ZZ})$, is shielded more than other components. In the direction of the $p(\pi)$ orbital of carbenic carbon atom (XX), the shield effect is not as significant as that in the ZZ direction, but it is still $\sim 300$ (BP86/BS-B and BP86/BS-C) and 350 ppm (B3LYP/BS-B and B3LYP/BS-C) stronger than the YY component where the attack of nucleophilic regents may take place.

The ${ }^{19}$ F NMR of $\mathbf{1 b}$ was recalculated with the GIAO approach, the improved estimations are given in parentheses in Table 6.3. HF is chosen as secondary reference which was optimized at the same theoretical level as for $\mathbf{1 b}$. The calculated ${ }^{19} \mathrm{~F}$ NMR value of $\mathbf{1 b}$ respective to HF is converted to the standard $\mathrm{CCl}_{3} \mathrm{~F}$ scale of $214 \mathrm{ppm} .{ }^{150 \mathrm{~b}, 160}$

$$
\delta\left({ }^{19} \mathrm{~F} \text { of } \mathbf{1 b}\right)=\sigma\left({ }^{19} \mathrm{~F} \text { of } \mathbf{1 b}\right)-\sigma\left({ }^{19} \mathrm{~F} \text { of } \mathrm{HF}\right)-214 \mathrm{ppm} \quad(\mathrm{Eq} 6.1)
$$

In this way, the calculated ${ }^{19} \mathrm{~F}$ NMR chemical shift for $\mathbf{1 b}$ with BS-C is about $\delta 180 \mathrm{ppm}$ (BP86) and $\delta 163 \mathrm{ppm}$ (B3LYP), respectively.

### 6.4 Summary and Conclusion

The calculated geometry of $\mathbf{1 b}$ shows that the carbene ligand $\mathrm{CF}_{2}$ prefers to coordinate equatorially to iron in a trigonal bipyramidal configuration, but the preference is very weak. The $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ bond in $\mathbf{1 b}$ is $\sim 20 \mathrm{kcal} / \mathrm{mol}$ stronger than the $\mathrm{Fe}-\mathrm{C}$ bond in the parent complex $\mathbf{2}$. The bonding analysis shows that $\mathbf{1 b}$ can be considered as a donor-acceptor complex (Fischer-type carbene complex). The calculated ${ }^{13} \mathrm{C}$ NMR data of $\mathbf{1 b}$ is reliable when $\mathbf{2}$ is used as secondary reference.

## Chapter 7. Summary

In this thesis, equilibrium geometries, bond dissociation energies and relative energies of axial and equatorial iron tetracarbonyls $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}\left(\mathrm{~L}=\mathrm{CO}, \mathrm{CS}, \mathrm{N}_{2}, \mathrm{NO}^{+}\right.$, $\mathrm{CN}^{-}, \mathrm{NC}^{-}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}, \mathrm{CF}_{2}, \mathrm{NH}_{3}, \eta^{2}-\mathrm{H}_{2}, \mathrm{NF}_{3}, \mathrm{PH}_{3}, \mathrm{PF}_{3}$ ) are calculated using density functional theory (B3LYP) and effective-core potentials with a valence basis set of DZP quality for iron and $6-31 G(d)$ all-electron basis sets for the other elements. The theoretically predicted structural parameters are in very good agreement with previous theoretical results and with available experimental data. Improved estimates for the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{L}$ bond dissociation energies $\left(\mathrm{D}_{\mathrm{o}}\right)$ are obtained using the $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II} / \mathrm{B} 3 \mathrm{LYP} / \mathrm{II}$ combination of theoretical methods. The strongest $\mathrm{Fe}-\mathrm{L}$ bonds are found for those complexes involving $\mathrm{NO}^{+}, \mathrm{CN}^{-}, \mathrm{CH}_{2}$ and $\mathrm{CCH}_{2}$ with bond dissociation energies of 105.1, $96.5,87.4$ and $83.8 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. These values decrease to $78.6,64.3$ and $64.2 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively, for $\mathrm{NC}^{-}, \mathrm{CF}_{2}$ and CS. The $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ complexes with $\mathrm{L}=\mathrm{CO}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{NH}_{3}, \mathrm{PH}_{3}$ and $\mathrm{PF}_{3}$ have even smaller bond dissociation energies ranging from 45.2 to 37.3 kcal $\mathrm{mol}^{-1}$. Finally, the smallest bond dissociation energies of $23.5,22.9$ and 18.5 kcal $\mathrm{mol}^{-1}$, respectively are found for the ligands $\mathrm{NF}_{3}, \mathrm{~N}_{2}$ and $\eta^{2}-\mathrm{H}_{2}$. A detailed examination of the $(\mathrm{CO})_{4} \mathrm{Fe}-\mathrm{L}$ bond in terms of a quantitative Dewar-ChattDuncanson (DCD) model using the CDA method and NBO analyses reveals a general trend that is consistent with the classical picture of the ligand site preference in trigonal bipyramidal $\mathrm{Fe}\left(\mathrm{d}^{8}\right)$-complexes. Hence, by comparing relative energies of the axial and the equatorial isomers of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ with the relative $\sigma$-donor $/ \pi$-acceptor strengths of the various ligands L , it is found that exclusively $\pi$-accepting ligands like $\mathrm{NO}^{+}$prefer equatorial coordination sites, whereas the strong $\sigma$-donors $\mathrm{CN}^{-}, \mathrm{NC}^{-}$ preferably coordinate axially. Although this behaviour is less obvious for moderately strong $\sigma$-donors like $\mathrm{NH}_{3}, \mathrm{NF}_{3}, \mathrm{PH}_{3}$, and $\mathrm{PF}_{3}$, a distinct axial preference is noticeable. Ligands like CS and $\mathrm{N}_{2}$ have $\sigma$-donor $/ \pi$-acceptor ratios close to unity leading to energetically likewise favourable isomers, thus indicating an indifferent attitude towards axial and equatorial coordination sites. However, exception has been found for $\mathrm{L}=\mathrm{C}_{2} \mathrm{H}_{4}, \mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}, \mathrm{CF}_{2}, \mathrm{H}_{2}$.

Quantum chemical calculations at the NL-DFT (B3LYP) and $\operatorname{CCSD}(\mathrm{T})$ levels of theory have also been carried out for the carbon complex $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{C}$. The bonding situation was analyzed with the NBO partitioning scheme and with the topological analysis of the electron density distribution. The results have been compared with the bonding situations in $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CH}_{2}, \mathrm{I}(\mathrm{CO})_{3} \mathrm{FeCH}$ and $\mathrm{Fe}(\mathrm{CO})_{5}$. The trigonalbipyramidal complex $(\mathrm{CO})_{4} \mathrm{FeC}$ with an axial $\mathrm{Fe}-\mathrm{C}$ bond is a minimum on the singlet potential energy surface, while the equatorial form is a transition state. The $\mathrm{Fe}-\mathrm{C}$ bond has a large dissociation energy $\mathrm{D}_{\mathrm{e}}=84.1 \mathrm{kcal} / \mathrm{mol}$ at B3LYP/II and $\mathrm{D}_{\mathrm{e}}=94.5$ $\mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II}$. The carbon ligand is a strong $\pi$-acceptor and an even stronger $\sigma$ donor. The analysis of the electronic structure suggests that $(\mathrm{CO})_{4} \mathrm{FeC}$ should behave like a carbon nucleophile. Geometry optimization of the donoracceptor complex $(\mathrm{CO})_{4} \mathrm{FeC}-\mathrm{BCl}_{3}$ yielded a strongly bonded compound which has a calculated C-B bond energy of $\mathrm{D}_{\mathrm{e}}=25.6 \mathrm{kcal} / \mathrm{mol}$ at B3LYP/II and $27.1 \mathrm{kcal} / \mathrm{mol}$ at $\operatorname{CCSD}(\mathrm{T}) /$ III, respectively. Lewis acid stabilized carbon complexes like $(\mathrm{CO})_{4} \mathrm{FeC}$ $\mathrm{BCl}_{3}$ might be isolated under appropriate conditions.

Theoretical studies using density functional theory (DFT) at the B3LYP level of theory and at the $\operatorname{CCSD}(\mathrm{T})$ level of theory are reported for mononuclear and dinuclear iron carbonyl complexes with the nitrogen-ligands $\mathrm{N}_{2}, \mathrm{~N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}$, and $\mathrm{NH}_{3}$ bound to the metal. The reaction enthalpies $\left(\Delta \mathrm{H}^{\circ}\right)$ for the hydrogenation steps of free $\mathrm{N}_{2}$ are well reproduced when relative large basis sets like $6-311+\mathrm{G}(\mathrm{d}, \mathrm{p})$ are used for N and H . The respective $\Delta \mathrm{H}^{\circ}$-values are 45.3(51.9), -22.4 (-18.3), -44.1(-43.5) kcal $\mathrm{mol}^{-1}$ for the formation of $\mathrm{N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}$, and $\mathrm{NH}_{3}$ at the $\operatorname{B3LYP}(\operatorname{CCSD}(\mathrm{T}))$ level of theory, respectively. For the reaction involving nitrogen coordinated to the $\mathrm{Fe}(\mathrm{CO})_{4}$ complex fragment, activation of $\mathrm{N}_{2}$ is found for the first reaction step yielding coordinated $\mathrm{N}_{2} \mathrm{H}_{2}$. The reaction energy is reduced by more than $14 \mathrm{kcal} \mathrm{mol}^{-1}$ compared to the analogous reaction of free $\mathrm{N}_{2}$. This trend is even stronger for the dinuclear iron carbonyl complex $\left[\mathrm{Fe}(\mathrm{CO})_{4}\right]_{2} \mathrm{~N}_{2}$ where $\Delta \mathrm{H}^{\circ}$ for the first hydrogenation step is lower by $18.2 \mathrm{kcal} \mathrm{mol}^{-1}$. In contrast to the first reaction step, the last two steps (from $\mathrm{N}_{2} \mathrm{H}_{2}$ via $\mathrm{N}_{2} \mathrm{H}_{4}$ to $\mathrm{NH}_{3}$ ) show almost no catalytic effect by the iron tetracarbonyl complex fragments.

The structure and NMR chemical shifts of the iron carbene complex $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ were calculated at the NL-DFT (BP86 and B3LYP) level with three
different basis sets. The calculated geometries indicate that the carbene ligand occupies an equatorial position in the trigonal bipyramidal complex, however with a weak site preference. No minimum was found for the axial isomer. The nature of the bonding between iron and carbene ligand in the Fischer-type complex was examined. The Fe - $\mathrm{C}_{\text {carbene }}$ bond strength $\left(\mathrm{D}_{\mathrm{o}}=63.8 \mathrm{kcal} / \mathrm{mol}\right)$ of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}(\mathrm{eq})$ is higher ( $\sim 20 \mathrm{kcal} / \mathrm{mol}$ ) than that of $\mathrm{Fe}-\mathrm{CO}$ in its parent complex $\mathrm{Fe}(\mathrm{CO})_{5}$ at the $\operatorname{CCSD}(\mathrm{T})$ level. The barrier to rotation of equatorial $\mathrm{CF}_{2}$ ligand around $\mathrm{Fe}-\mathrm{C}_{\text {carbene }}$ axis in $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ (eq) was estimated to be lower than $14.1 \mathrm{kcal} / \mathrm{mol}$ at the BP86 level. ${ }^{13} \mathrm{C}$ and ${ }^{19} \mathrm{~F}$ NMR chemical shifts of $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ (eq) were calculated for the first time using the GIAO method. With theoretical calculations as a guidance, it is suggested that the ${ }^{13} \mathrm{C}$ NMR resonance of the carbonyl carbon atom almost does not change when it goes from the parent complex $\mathrm{Fe}(\mathrm{CO})_{5}$ to substituted $(\mathrm{CO})_{4} \mathrm{FeCF}_{2}$ (eq). The carbenic C atom is much more deshielded ( $\sim 40 \mathrm{ppm}$ ) with respect to the CO ligand at both BP86 and B3LYP. The ${ }^{19}$ F NMR chemical shift is predicted to be in the range of 160-180 ppm combining the results from DFT-GIAO calculations.

## Zusammenfassung

In der vorliegenden Arbeit wurden die Gleichgewichtsstrukturen und relativen Energien von $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ Komplexen mit den Liganden $\mathrm{L}=\mathrm{CO}, \mathrm{CS}, \mathrm{N}_{2}, \mathrm{NO}^{+}, \mathrm{CN}^{-}$, $\mathrm{NC}^{-}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}, \mathrm{CF}_{2}, \eta^{2}-\mathrm{H}_{2}, \mathrm{NH}_{3}, \mathrm{NF}_{3}, \mathrm{PH}_{3}$ und $\mathrm{PF}_{3}$ mittels DFT-Rechnungen und nichtrelativistischem Pseudopotential (ECP) für Eisen sowie Standard-Basissätzen (DZP) für die Liganden untersucht. Für zuverlässige Dissoziationsenergien $\left(\mathrm{D}_{\mathrm{o}}\right)$ wurden single point $\operatorname{CCSD}(\mathrm{T})$-Energien auf den B3LYPGeometrien gerechnet. Die stärksten Fe-L-Bindungen ergeben sich für die Komplexe mit den Liganden $\mathrm{L}=\mathrm{NO}^{+}, \mathrm{CN}^{-}, \mathrm{CH}_{2}$ und $\mathrm{CCH}_{2}$ von 105.1, 96.5, 87.4 und 83.8 kcal $\mathrm{mol}^{-1}$. Es folgen die Komplexe mit $\mathrm{L}=\mathrm{NC}^{-}, \mathrm{CF}_{2}$ und CS , mit $\mathrm{D}_{0}$-Werten von 78.6, 64.3 , und $64.2 \mathrm{kcal} \mathrm{mol}^{-1}$. Die Komplexe mit $\mathrm{L}=\mathrm{CO}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{4}, \eta^{2}-\mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{NH}_{3}, \mathrm{PH}_{3}$ und $\mathrm{PF}_{3}$ haben kleinere Bindungsenergien von 45.2 bis $37.3 \mathrm{kcal} \mathrm{mol}^{-1}$. Die niedrigsten Dissoziationsenergien von 23.5, 22.9 und $18.5 \mathrm{kcal} \mathrm{mol}^{-1}$ ergeben sich für die Komplexe mit $\mathrm{L}=\mathrm{NF}_{3}, \mathrm{~N}_{2}$ und $\eta^{2}-\mathrm{H}_{2}$. Zur Analyse der Fe-L Donor-AkzeptorWechswickung wurden die CDA (Charge Decomposition Analysis) und NBO (Natural Bond Orbital) Methoden verwendet. Die Ergebnisse zeigen, daß die bevorzugte Stellung eines Liganden L in axialer oder äquatorialer Stellung in einem fünffach koordiniertem Komplex mit trigonal-bipyramidaler Anordnung in guter Übereinstimmung mit klassischen Vorstellungen sind. Ein Vergleichen zwischen der relativen $\sigma$-Donor/ $\pi$-Akzeptor-Starke der Liganden L und der Stabilität von äqutorialen bzw. axialen Isomeren der Komplexe $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{~L}$ zeigt, daß $\mathrm{NO}^{+}$als $\pi$ Akzeptor eine äquatoriale Stellung bevorzugt. Als starke $\sigma$-Donor werden $\mathrm{CN}^{-}$und $\mathrm{NC}^{-}$in der axialen Position gebunden. Eine klare Bevorzugung der axialen Stellung wird für relativ starke $\sigma$-Donor $\mathrm{NH}_{3}, \mathrm{NF}_{3}, \mathrm{PH}_{3}$, und $\mathrm{PF}_{3}$ gefunden. Wegen der ähnlich starken $\sigma$-Donierung und $\pi$-Rückdonierung ergeben sich für die Komplexe mit $\mathrm{L}=\mathrm{CS}$ und $\mathrm{N}_{2}$ keine bevorzugte Koordinationsstelle. Ausnahme wird für die Liganden $\mathrm{C}_{2} \mathrm{H}_{4}, \mathrm{C}_{2} \mathrm{H}_{2}, \mathrm{CCH}_{2}, \mathrm{CH}_{2}, \mathrm{CF}_{2}$ and $\mathrm{H}_{2}$ gefunden.

Die quantenchemischen Rechnungen von Carbonkomplex $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{C}$ wurden auf dem B3LYP- und $\operatorname{CCSD}(\mathrm{T})$-Niveau durchgeführt. Die Bindungsverhältnisse wurden mittels der NBO und der AIM-Methoden untersucht. Die Ergebnisse wurden mit den

Daten des Carbenkomplexes $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CH}_{2}$, des Carbinkomplexes $\mathrm{I}(\mathrm{CO})_{3} \mathrm{FeCH}$ und des Carbonylkomplexes $\mathrm{Fe}(\mathrm{CO})_{5}$ verglichen. Der trigonal-bipyramidale Komplex $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{C}$ mit axialer $\mathrm{Fe}-\mathrm{C}_{\text {carbon }}$ Bindung ist ein Minimum auf der Singulett Potential-Energie-Fläche. Die äquatoriale Form ist ein Übergangszustand. Die Bindungsenergie von $\mathrm{Fe}-\mathrm{C}$ in $(\mathrm{CO})_{4} \mathrm{FeC}(\mathrm{ax})$ ist mit $\mathrm{D}_{\mathrm{e}}=94.5 \mathrm{kcal} / \mathrm{mol}$ sehr stark. Der KohlenstoffLigand ist ein starker $\pi$-Akzeptor und noch stärkerer $\sigma$-Donor. Die Analyse der elektronischen Struktur zeigte, daß der Kohlenstoff-Ligand des Komplexes (CO) ${ }_{4} \mathrm{FeC}$ nukleophile Eigenschaft haben sollte. Die Geometrieoptimierung des Donor-Akzeptor-Komplexs $(\mathrm{CO})_{4} \mathrm{FeC}-\mathrm{BCl}_{3}$ ergibt einen stark gebunden Komplex, der eine C-B-Bindungsenergie von $\mathrm{D}_{\mathrm{e}}=27.1 \mathrm{kcal} / \mathrm{mol}$ auf $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II}-$ Niveau hat. Der von der Lewis-Säure stabilisierte Carbonkomplex $(\mathrm{CO})_{4} \mathrm{FeC}-\mathrm{BCl}_{3}$ ist unter günstigen Bedingungen zu isolieren.

Die theoretischen Untersuchungen über die mit Stickstoff-Liganden $\mathrm{N}_{2}, \mathrm{~N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}$, und $\mathrm{NH}_{3}$ koordinierten Eisenkomplexe wurden mit der DFT-Methode B3LYP durchgeführt. Die Reaktionsenthalpie $\Delta \mathrm{H}^{\circ}$ wurde auf $\operatorname{CCSD}(\mathrm{T})$-single-point Niveau berechnet. Bei Verwendung relativ großer Basissätze ( $6-311+\mathrm{G}(\mathrm{d}, \mathrm{p})$ ) sind die berechneten $\Delta \mathrm{H}^{\circ}-$ Werte für die Reaktion von $\mathrm{N}_{2} \mathrm{zu} \mathrm{NH} \mathrm{NH}_{3}$ in guter Übereinstimmung mit experimentellen Daten. Die $\Delta \mathrm{H}^{\mathrm{o}}$-Werte auf B3LYP ( $\operatorname{CCSD}(\mathrm{T})$ )-Niveau sind 45.3 (51.9), -22.4 (-18.3), -44.1 (-43.5) $\mathrm{kcal} \mathrm{mol}^{-1}$ für die Bildung der Moleküle $\mathrm{N}_{2} \mathrm{H}_{2}, \mathrm{~N}_{2} \mathrm{H}_{4}$, und $\mathrm{NH}_{3}$. Bei den das mononukleare $\mathrm{Fe}(\mathrm{CO})_{4}$-Fragment erhaltenen Reaktionen ist eine $\mathrm{N}_{2}$-Aktivierung gefunden worden. Die benötige Energie zur Bildung von koordiniertem $\mathrm{N}_{2} \mathrm{H}_{2}$ ist $14 \mathrm{kcal} \mathrm{mol}^{-1}$ geringer als die analoge nichtkatalysierte Reaktion. Dieser Trend ist noch stärker für die Reaktion mit dem dinuklearen Fe -Fragment. Der $\Delta \mathrm{H}^{\mathrm{o}}$-Wert beträgt hier nur $18.2 \mathrm{kcal} \mathrm{mol}^{-1}$. Im Vergleichen zu diesem ersten Schritt zeigt sich, daß die zwei nachfolgenden Schritten keinen Katalyseeffekt der $\mathrm{Fe}(\mathrm{CO})_{4}$-Fragmente aufweisen.

Die Struktur und chemische Verschiebungen des Eisenkomplexes $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CF}_{2}$ wurden auf dem NL-DFT-Niveau (BP86 und B3LYP) mit drei verschiedenen Basissätzen untersucht. Im stabilsten Isomer ist $\mathrm{CF}_{2}$ äquatorial koordiniert. Die Energiedifferenz zwischen axialen und äquatorialen Isomer ist aber sehr gering. Bei der ${ }^{13} \mathrm{C}$-NMR-Berechnung gibt es keine Änderung für den Carbonyl-Kohlenstoff vom Carbonylkomplex $\mathrm{Fe}(\mathrm{CO})_{5}$ hin zum Carbenkomplex $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{CF}_{2}$. Dagegen ist der

Carben-Kohlenstoff mehr als 40 ppm abgeschirmt. Aus den berechneten ${ }^{19} \mathrm{~F}$ chemischen Verschiebungen kann man abschätzen, daß der Wert im Bereich 160-180 ppm sein sollte.

BSSE and basis set incompletion error (BSIE) have opposite sign and are computational artefacts due to the use of a truncated and incomplete basis set. Approaches like the counterpoise correction [Boys, S. F.; Bernardi, F. Mol. Phys. 1970, 553.] only account for the BSSE and leave the BSIE uncorrected. A more saturated basis set would in principle correct both BSSE and BSIE but would also make such computations quite uneconomical in terms of computational resource usage. We therefore think that for a comparison with experimental data directly calculated results should be used rather than estimated data. A detailed discussion is given in Refs 33 and 37.
The residual term $\Delta$ is close to zero for all complexes examined in this study thus showing that the $\mathrm{Fe}-\mathrm{L}$ bond of these complexes can indeed be described in terms of the conventional DCD model. Large $\Delta$-values on the other hand would imply rather covalent bonds, which should not be discussed in terms of donor-acceptor interactions. For a detailed discussion see: Ref. 38 and Fröhlich, N; Frenking, G. in Solid State Organometallic Chemistry: Methods and Applications, Gielen, M.; Willem, R.; Wrackmeyer, B. (Eds), John Wiley and Sons: New York, 1999.

At the B3LYP/II level of theory, the ${ }^{1} \mathrm{~A}_{1}$ state of $\mathrm{Fe}(\mathrm{CO})_{4}$ is higher in energy than the ${ }^{3} \mathrm{~B}_{2}$ state by $8.3 \mathrm{kcal} \mathrm{mol}^{-1}$. A detailed discussion of singlet $v s$. triplet $\mathrm{Fe}(\mathrm{CO})_{4}$ is given in: (a) Poliakoff, M.; Turner, J. J. J. Chem. Soc., Dalton Trans. 1974 2276. Touchard, D.; Fillaut, J-L.; Dixneuf, P. H.; Toupet, L. J. Organomet. Chem. 1986, 317, 291.

Only one side-on isomer $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}\right.$-CS), with CS occupying an equatorial coordination site is found. Compared to its corresponding end-on counterpart this complex is less stable by $34 \mathrm{kcal} \mathrm{mol}^{-1}$. The linkage isomer $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{SC}$ is even less favourable and this energy difference is increased to $50 \mathrm{kcal} \mathrm{mol}^{-1}$.
Corresponding side-on dinitrogen iron tetracarbonyls $\mathrm{Fe}(\mathrm{CO})_{4}\left(\eta^{2}-\mathrm{N}_{2}\right)$ are found to be at least $10 \mathrm{kcal} \mathrm{mol}^{-1}$ less stable than the presented end-on isomers.

97 The authors of Ref. 50 only consider structures of $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PH}_{3}$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PF}_{3}$ in which the phosphanes are staggered with respect to the three equatorial COs. According to our $\operatorname{CCSD}(\mathrm{T}) / \mathrm{II}$ calculations, the eclipsed conformer is more stable for both complexes. At the B3LYP/II level, the relative energies of these two conformations are, however, very small and only 0.1 and $1.2 \mathrm{kcal} \mathrm{mol}^{-1}$ for $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PH}_{3}$ and $\mathrm{Fe}(\mathrm{CO})_{4} \mathrm{PF}_{3}$, respectively. 107 Another bonding model for 1a would be a shared-electron double bond between the unpaired electrons of triplet $\mathrm{Fe}(\mathrm{CO})_{4}$ and the unpaired electrons of carbon in the triplet ground state. This leads to an iron atom in the formal oxidation state +2 and a carbon ligand with the formal charge 2 , which is a rather unrealistic views.

111 Hoffmann, R. Angew. Chem. 1982, 94, 725; Angew. Chem. Int. Ed. Engl. 1982, 21, 711.

112 The calculated ${ }^{3} \mathrm{P} \rightarrow{ }^{1} \mathrm{D}$ excitation energy at B3LYP/II ( $44.1 \mathrm{kcal} / \mathrm{mol}$ ) and $\operatorname{CCSD}(\mathrm{T}) / I I(37.1 \mathrm{kcal} / \mathrm{mol})$ is too high because of the poor description of the ${ }^{1} \mathrm{D}$ state at the one-determinant level.

115 The calculated small positive charge of the carbon atom in 1a does not contradict the classification of the carbon ligand as a nucleophile. Carbon monoxide also reacts as C-nucleophilic agent, although the carbon atom of CO carries a positive charge. The shape of the charge distribution has a stronger influence on the chemical reactivity than the atomic partial charge.

### 9.5 Abbreviations

| AIM | atoms in molecules |
| :--- | :--- |
| CC | coupled cluster |
| CCSD(T) | coupled cluster singles, doubles and estimated triples <br> charge decomposition analysis |
| CDA | configuration interaction |
| CI | CI with all single and double substitutions from the Hartree-Fock reference <br> CISD |
| determinant |  |

[^0]:    ${ }^{\mathrm{a}}$ see ref $75 \mathrm{a}{ }^{\mathrm{b}} \mathrm{C}-\mathrm{O}: 2103,2100,2000 \mathrm{~cm}^{-1} \quad{ }^{\mathrm{c}} \mathrm{Fe}-\mathrm{C}: 465 \mathrm{~cm}^{-1}$ is listed here for both isomers for comparison.

[^1]:    ${ }^{a}$ Keyword for 3-center bond was used

[^2]:    ${ }^{\mathrm{a}} \rho\left(\mathrm{r}_{\mathrm{b}}\right), \mathrm{H}_{\mathrm{b}}, \nabla^{2} \rho\left(\mathrm{r}_{\mathrm{b}}\right)$ are the electron density, the energy density, Laplacian at the bond critical point $r_{b}$, respectively. $R\left(X-r_{b}\right)$ and $R\left(r_{b}-Y\right)$ give the distance between the bond critical point $\mathrm{r}_{\mathrm{b}}$ and the X or Y atom.

[^3]:    ${ }^{\text {a }}$ respective to $\mathrm{CH}_{4}$.
    ${ }^{\mathrm{b}}$ using BP86/BS-A optimized geometry.
