

Analysis of the spore formation process in *Myxococcus xanthus*

DISSERTATION

zur Erlangung des Doktorgrades der Naturwissenschaften
(Dr. rer. nat.)

dem
Fachbereich Biologie
der Philipps-Universität Marburg

vorgelegt von

Frank-Dietrich MÜLLER

aus Zwickau

Marburg/Lahn im Januar 2009

Vom Fachbereich Biologie der Philipps-Universität Marburg als Dissertation am

_____ angenommen.

Erstgutachter: Prof. Dr. MD Lotte Søgaaard-Andersen

Zweitgutachter: Prof. Dr. Renate Renkawitz-Pohl

Tag der mündlichen Prüfung: 31.03.2009

Die Untersuchungen zur vorliegenden Arbeit wurden von Dezember 2005 bis November 2008 am Max-Planck-Institut für terrestrische Mikrobiologie Marburg unter der Leitung von Dr. Penelope I. Higgs durchgeführt.

*

Die während der Promotion erzielten Ergebnisse wurden und werden in folgenden Originalpublikationen veröffentlicht:

Müller, F.-D. & Jakobsen, J. S. (2008). Expression analysis. In: Myxobacteria. Multicellularity and Differentiation. D. E. Whitworth (ed). Washington, D.C.: ASM Press, pp. 479 - 489.

KURZFASSUNG

Myxococcus xanthus ist ein Vertreter Gram-negativer Bakterien, die die Fähigkeit besitzen, als Antwort auf sich verschlechternde Umweltbedingungen widerstandsfähige und metabolisch inaktive Sporen zu bilden. Im Gegensatz zu bereits gut untersuchten Gram-positiven Modellorganismen, die Sporen durch spezialisierte Zellteilung hervorbringen, werden *M. xanthus*-Sporen durch Abrunden vollständiger, stäbchenförmiger Zellen gebildet. Die Sporulation erfolgt normalerweise innerhalb multizellulärer Fruchtkörper als letztes Stadium eines komplizierten, durch Nährstoffmangel induzierten Entwicklungsprogramms. Die Analyse des Sporulationsprozesses wird durch das Auftreten nicht sporulierender Teilpopulationen innerhalb einer sich differenzierenden Kolonie sowie den geringen Anteil der tatsächlich sporenbildenden Zellen und die hohe Widerstandsfähigkeit der Sporen nachhaltig erschwert. Deshalb wurde in der vorliegenden Arbeit die glycerininduzierte, synchrone Sporulation als Modell für den Differenzierungsprozess vegetativer *M. xanthus*-Zellen in resistente, sphärische Sporen genutzt. Eine Transkriptomanalyse der glycerin-induzierten Zellen mit Hilfe von Microarrays ergab, dass während der ersten vier Stunden nach erfolgter Induktion 1.596 Gene mindestens zweifach höher oder niedriger transkribiert werden, als in vegetativen Zellen. Es konnte gezeigt werden, dass die Gruppe der differentiell regulierten Gene die meisten der bisher beschriebenen sporulationspezifischen Markergene enthält, nicht jedoch Gene, die für Aggregation und Fruchtkörperbildung spezifisch sind. Diese Ergebnisse zeigen, dass die Glycerininduktion speziell den Sporulationsprozess aktiviert und als Modellsystem für die Differenzierung vegetativer *M. xanthus*-Zellen geeignet ist.

Die Analyse der Microarraydaten führte zur Identifikation eines bisher unbeschriebenen Genclusters, der als *nfs* (*n*ecessary *f*or *s*porulation) bezeichnet wurde. Alle acht hier codierten Proteine besitzen keine Homologie zu bereits charakterisierten Proteinen. *In-frame*-Deletion aller acht Gene führte zu einem Defekt sowohl in glycerin- als auch in nährstoffmangelinduzierter Sporenbildung, während Aggregation und Fruchtkörperbildung nicht beeinträchtigt waren. Von der *nfs*-Promotorregion ausgehende Transkription war 30 Minuten nach Glycerininduktion und während nährstoffmangelinduzierter Sporulation ausschließlich in der sporenbildenden Subpopulation nachweisbar. Diese Ergebnisse lassen darauf schließen, dass die *nfs*-Gene den zentralen Sporulationsgenen zugehören. Die glycerininduzierte Sporulation führte zu vorübergehendem Auftreten morphologisch aberranter Zellen. Die Analyse verschiedener Entwicklungsmutanten weist außerdem darauf hin, dass die Expression der *nfs*-Gene während nährstoffmangelinduzierter Sporulation C-Signal abhängig ist und durch FruA kontrolliert wird. Zellfraktionierung, Bioinformatik- und Immunoblot-Analysen legen nahe, dass die Nfs-Proteine mit der Zellhülle assoziiert sind und interagieren. Die Ergebnisse lassen insgesamt darauf schließen, dass die Nfs-Proteine für die Bildung widerstands- und lebensfähiger Sporen essentiell sind und einen speziell während der Sporulation gebildeten und in der Zellhülle verankerten Komplex bilden.

Darüber hinaus wurde die Rolle des filament- und cytoskelettbildenden Proteins MreB bei der Zellform-Konversion während der Sporenbildung und Sporenkeimung in *M. xanthus* untersucht. MreB ist in den meisten stäbchenförmigen Bakterien maßgeblich an der Aufrechterhaltung der Zellform sowie an Wachstums- und Zellteilungsprozessen beteiligt. Immunoblot-Analysen legen nahe, dass MreB während glycerininduzierter Sporenbildung in vergleichbaren Mengen erhalten bleibt, während nährstoffmangel-induzierter Sporenbildung jedoch abgebaut wird. Dies deutet an, dass alternative Mechanismen der Zellformkonversion in *M. xanthus* existieren. Ferner weist die Analyse der Sporenkeimung in Gegenwart der MreB-destabilisierenden Verbindung A22 darauf hin, dass die Bildung polymerer MreB-Filamente einen wesentlichen Schritt während des Keimungsprozesses, also während der Konversion sphärischer Zellen in stäbchenförmige, darstellt.

Die in dieser Arbeit erzielten Ergebnisse eröffnen die Möglichkeit, mit Hilfe von *M. xanthus* als Modellorganismus fundamentale Mechanismen der Entstehung bakterieller Zellmorphologie, gesteuerter Konversion der Zellform, Zellwandsynthese und Bildung resistenter Sporen in Gram-negativen Bakterien zu entschlüsseln.

ABSTRACT

Myxococcus xanthus is a representative of Gram-negative bacteria that are able to form quiescent, environmentally-resistant spores in response to changes in environmental conditions, such as nutrient depletion. *M. xanthus* spores are formed inside fruiting bodies as final stage of an elaborate developmental program. In contrast to well studied Gram-positive spore formers, where sporulation is linked to cell division, *M. xanthus* spores are formed by rounding up of an entire rod-shaped cell. Studies on the core sporulation process in *M. xanthus* are impeded by the complexity of the starvation induced developmental program, subpopulations within a developing colony, the low proportion of cells that convert into spores, and their high mechanical resistance. We took advantage of the glycerol induced spore formation process and performed micro array analysis. This study revealed that 1,596 genes are significantly at least two-fold up- or down-regulated within four hours after addition of the inducer. Most of the genes that previously have been identified to play a role during starvation induced sporulation were found to be up-regulated indicating that the glycerol induced sporulation is an appropriate model to study the core sporulation process in *M. xanthus*.

The array data analysis led to identification of a novel and highly up-regulated genomic locus termed *nfs* (*n*ecessary *f*or *s*porulation). The *nfs* locus encodes for eight proteins that show no homology to characterized proteins. Bioinformatics, mutational and immunoblot analysis suggest that the Nfs-proteins localize to the cell envelope and form a complex. In-frame deletion of the *nfs*-genes led to a severe defect both in glycerol and starvation induced sporulation, whereas aggregation was not affected. In response to glycerol induction, the Δnfs mutant displayed transiently aberrant cell morphology. Transcription from the *nfs*-promoter was detectable 30 minutes after induction with glycerol. Translational fusion of the putative promoter region to *mcherry* as reporter suggests that the *nfs*-genes only accumulate in spores. Analysis of *nfs*-expression in developmental mutant backgrounds suggests that *nfs*-expression is dependent on C-signaling and controlled by FruA. Based on this observation it is hypothesized that the Nfs proteins are specifically expressed during spore formation, that they form a cell envelope-associated complex and that they play a crucial role in generating viable spores.

In addition, the role of the filament-forming cytoskeletal protein MreB was analyzed in respect to spore formation using genetic and biochemical approaches. MreB plays a crucial role in maintaining a rod-like cell shape in most known rod-shaped bacteria and has been shown to be a key-organizer of cell wall synthesis. The results suggest that the protein stays present during glycerol induced spore formation but becomes degraded during starvation induced spore formation suggesting two alternative ways of sphere formation in *M. xanthus*. Assays of spore germination with the MreB perturbing compound A22 revealed that MreB polymerization is an important precondition for germination of spherical spores, i.e. when cells re-establish rod-like cell morphology.

The results of this work could provide a set of tools that can be used to reveal fundamental mechanisms of cell shape determination and coordinated cell shape conversion during spore formation as well as peptidoglycan synthesis with respect to cell morphogenic events in Gram-negative bacteria.

ACKNOWLEDGEMENTS

I am deeply indebted to my supervisor Dr. Penelope I. Higgs for her guidance, suggestions and encouragement throughout my research and thesis.

I wish to express my sincere gratitude and appreciation to my thesis committee members, Prof. Dr. MD Lotte Søgaard-Andersen, Prof. Dr. Renate Renkawitz-Pohl, Prof. Dr. Martin Thanbichler and PD Dr. Michael Feldbrügge and my IMPRS thesis committee for their invaluable time for ideas, and comments.

A special thanks to Petra Mann for her excellent technical assistance throughout my work in Marburg. Moreover, I would like to thank Dr. Sigrun Wegener-Feldbrügge for help in micro array data analysis and constructive discussions and I am grateful to Dr. Kai Thormann for collaboration in confocal laser scanning microscopy. I also thank Dr. Stuart Huntley for his help in bioinformatics. I would also like to thank Anna-Lena Müller and Emöke Cserti for their technical help in the lab. I would like to extend my thanks to IMPRS coordinators Dr. Juliane Dörr (former), Dr. Ronald Brudler (present) and Susanne Rommel for their help in official issues.

I would like to gratefully acknowledge all colleagues from the Higgs lab for productive discussions. I thank all past and present members of the Department of Ecophysiology for providing a friendly working environment; and I would like to thank Dr. Jimmy Jakobsen and Steffi Lindow for their support at the beginning of my work.

In a special way, I would like to express my deepest gratitude to my family, for their encouragement and unconditional support throughout my life and in particular during my studies. In addition, I express my sincere thanks to all those who contributed to this thesis in one way or the other.

1 INTRODUCTION

1.1 Spore forming bacteria

Free living bacteria are exposed to changes of environmental conditions such as pH- or osmotic shifts, nutrient limitation and predation. These changes can exert physical or biochemical stresses. To survive under unfavorable conditions, many species have developed the ability to form resistant dormant stages as an adaptive response. These stages are characterized by decreased metabolic activity and increased resistance to harmful environmental traits such as desiccation, heat, UV-irradiation and enzymatic or mechanical disintegration (Sonenshein *et al.*, 1993, Whitworth, 2008). The most robust entities displaying large changes in metabolism, cell envelope structure and -shape are spores. The spore envelope forms the first and most important barrier against the detrimental factors acting from the surrounding milieu. A characteristic feature of spores is therefore an enhanced cell envelope consisting of modified cell wall and membranes, and they are surrounded by polymeric surface layers that are not found in vegetative cells.

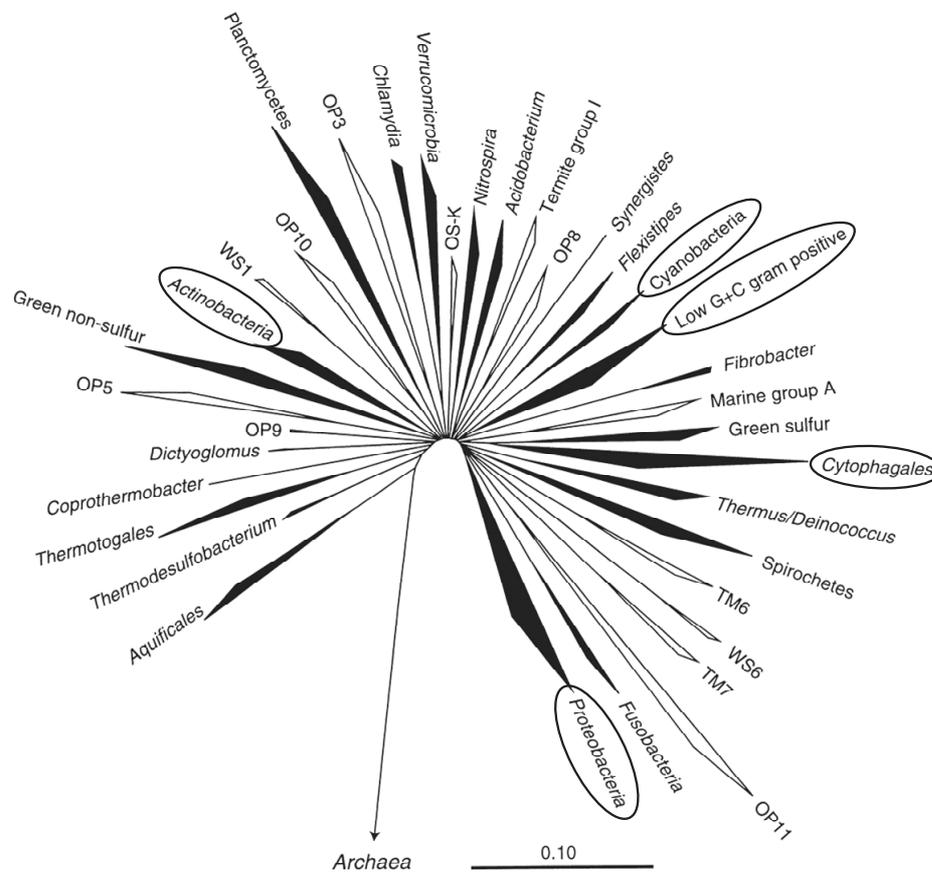

Figure 1-1 Proposed evolutionary distance tree of the bacterial domain showing recognized divisions and candidate divisions (taken from (Hugenholtz *et al.*, 1998)). Phyla containing characterized spore-forming species are circled.

The ability to form spores is known from a variety of bacteria. To date, the best studied model systems for bacterial spore formation are found in the Gram-positive *Bacillus*, *Clostridium* and *Streptomyces* species. In these bacteria, spore formation is accomplished by progression through distinct stages including initiation, chromosome segregation, sporulation-specific cell division (asymmetric in rod-shaped bacteria), differential gene expression and specific signal transduction mechanisms. This means that in Gram-positives, sporulation is generally connected to a distinct mechanism of cell division (Barak *et al.*, 2005). Interestingly however, resistant dormant stages are also known from Gram-negative bacteria such as *Sporocytophaga* sp. (Bacteroidetes/Cytophagales), Cyanobacteria, *Methylosinus*, *Methanobacterium*, *Rhodospirillum* and *Azospirillum* (Alphaproteobacteria), *Azotobacter* (Gammaproteobacteria) or Myxococcales species (Deltaproteobacteria) (**Figure 1-1**). Whereas the spore formation process in Gram-positives has been successfully studied for decades, sporulation in Gram-negative bacteria is poorly understood.

1.1.1 *Bacillus subtilis*

In *B. subtilis* (and similarly in *Clostridium* sp.), a complex set of inter- and intracellular signals is evaluated before a cell enters the sporulation pathway. Such signals are nutrient availability, glucose utilization and activity of the citrate and glyoxylate cycles, DNA integrity and state of chromosome replication. Initial key regulators are σ^H and the transcriptional regulator Spo0A whose activity is controlled by a phospho-relay system. Both factors control the expression of more than 500 genes (Barak *et al.*, 2005). If the sporulation process has been initiated, the cell is committed to proceed. A current round of chromosome replication is finished and initiation of a new cycle is prevented. The origin regions of the chromosomes are separated by moving and tethering them to opposite cell poles (**Figure 1-2 a**). Septum formation is initiated by the FtsZ protein that assembles into the Z ring which recruits the machinery necessary for cytokinesis (Carballido-Lopez & Formstone, 2007, Pichoff & Lutkenhaus, 2007). In contrast to vegetative cell division, the FtsZ-ring does not localize at midcell but instead asymmetrically at a polar site leading to transient trapping of one chromosome in the forming septum and placement of specific genes inside the forespore. To ensure that the emerging spore later contains one complete DNA molecule, the trapped DNA is actively pumped into the forespore by SpoIIIE. Further Spo0A~P accumulation is subsequently inhibited in the forespore but continues in the mother cell. This initiates unequal gene expression cascades in both compartments but there exists also a crosstalk between mother cell and the developing spore. Spo0A~P triggers indirectly expression of σ^E in the mother cell, whereas Spo0A~P disappears in the forespore leading to synthesis of σ^F (**Figure 1-2 a**). σ^F becomes active after the septum has formed, and generates a signal that activates σ^E in the mother cell. The forespore subsequently gets engulfed by the mother cell's membrane leading to a second membrane-layer surrounding the forespore. σ^G is subsequently activated in the spore and generates a signal that produces active σ^K in the mother cell. Subsequently, cortex material consisting of weakly cross-linked peptidoglycan is synthesized between the two spore membranes and deposited as spore cortex. The spore coat proteins are then synthesized in the mother cell and assembled on the cortex. Finally, the mother cell undergoes

autolysis and the spore is set free (reviewed in (Piggot & Losick, 2002), (Piggot & Hilbert, 2004) and (Errington, 2003)). The whole endospore forming process in *B. subtilis* takes about eight hours.

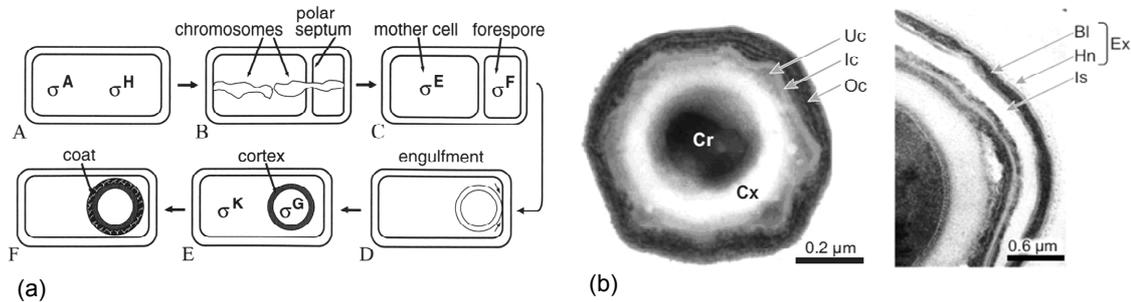

Figure 1-2 (a) Schematic view of spore formation in *Bacillus*, taken from (Kroos *et al.*, 2008). (b) Spore ultra structure. Cr: core, Cx: cortex, Uc: undercoat, Ic: inner coat, Oc: outer coat, Ex: exosporium, Bl: basal layer, Hn: glycoprotein nap, Is: inter space. Taken from (Waller *et al.*, 2004). See text for details.

1.1.2 The *Bacillus* endospore

The endospore is a complex, multi-layered structure (**Figure 1-2 b**). The DNA-containing core is surrounded by the inner spore membrane. This membrane is covered by two distinct layers of peptidoglycan, called cortex. The cortex is covered by a triple-layered coat consisting of peptides and proteins. Finally, the coat is enclosed in a loose-fitting glycoprotein structure termed exosporium. Both external layers encase an interspace compartment. Interestingly, all envelope components above the inner layer of the cortex are synthesized and deposited by the mother cell (Henriques & Moran, 2007). Hardening the spore against environmental traits involves desiccation and accumulation of small acid soluble proteins (Sasp's) that protect the spore DNA and serve as amino acid source during germination. Incorporation of dipicolinic acid in the cortex is also essential for resistance and germination (Magge *et al.*, 2008).

It appears that most proteins detected in the spore coat are structural proteins controlling their own multimeric assembly and that of the whole coat (Kim *et al.*, 2006). Interestingly, the coat proteins and peptides are frequently post-translationally modified by glycosylation, cross-linking, proteolytic processing or they are assembled in the mature coat in either homo- or heteromultimeric forms (Isticato *et al.*, 2004, Zilhao *et al.*, 2004). The function of the coat proteins is partially understood. Their major role in *B. subtilis* is to protect the spore from enzymatic and chemical attacks such as from hydrogen peroxide, chlorine dioxide or ozone (Setlow, 2006). A defective spore coat also compromises the spore cortex to lysozyme and renders the spore prone to digestion by protozoans (Klobutcher *et al.*, 2006). The exosporium known from other *Bacillus* species may help to escape phagocytosis in eukaryotic hosts (Henriques & Moran, 2007). Some of the spore coat proteins display enzymatic activities and are probably involved in sensing environmental conditions (Enguita *et al.*, 2002, Costa *et al.*, 2004). The coat proteins are also involved in control of germination (Bagyan & Setlow, 2002, Moir, 2006). Moreover, the entire coat structure can fold and unfold allowing adaptation to a changing spore volume such as shrinking during desiccation and swelling during germination.

1.1.3 Spore formation in *Streptomyces* spp.

A second model system for spore formation is the filamentous growing Gram-positive genus *Streptomyces*. In these bacteria, chains of spores are formed at the tips of distinct filaments that rise from the substrate. This means, in contrast to *Bacillus*, *Streptomyces* cells need to grow to form compartments that differentiate into spores.

The signals that initiate the differentiation process are not yet well characterized. Nutrient limitation as well as intercellular signaling plays a role. Detachment of the differentiating filaments from the substrate is facilitated by secretion of hydrophobic proteins. Upon spore formation, growth of these filaments ceases and single chromosomes are separated into pre-spore compartments (Figure 1-3). At least two distinct complex gene expression cascades have been identified to regulate the process (Ausmees *et al.*, 2007). The *bld* cascade regulates initiation of aerial growth (*bld* stands for *bald* because of the missing aerial hyphae), whereas the *whi* genes control later steps such as chromosome segregation and septum formation (*whi* stands for *white* because of abolished pigment synthesis) (Chater, 2001, Claessen *et al.*, 2006).

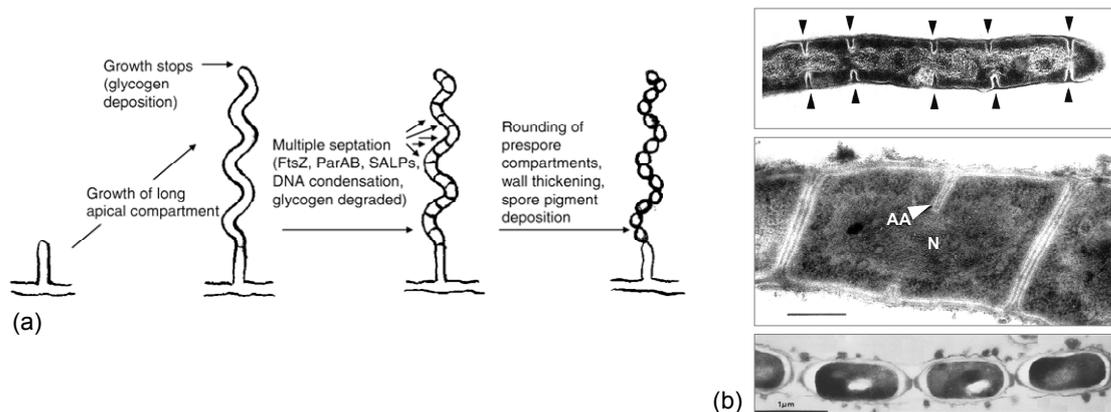

Figure 1-3 (a) Schematic view of spore formation in the Gram-positive filamentous *S. coelicolor* (taken from (Chater & Chandra, 2006)). (b) Process of spore formation in *Streptomyces* sp. shown by electron micrographs. Single spores are separated by growing sporulation septa. AA: Double edge of ingrowing annulus, N: nucleoid. Taken from (Hardisson & Manzanal, 1976) and (Vobis & Zimmermann, 1984).

Interestingly, *Streptomyces* lacks many cell division related genes essential for other bacteria such as *ftsA*, *minCD*, *ftsB*, *N* and others. Vegetative filaments septate only occasionally and even mutants unable to form septa are still viable. Therefore, the filamentous vegetative cells contain an unspecific number of chromosomes. Furthermore, the conserved cell division proteins *ftsZ*, *ftsQ* and *mreB* are dispensable for vegetative growth, but they are essential to septate and therefore to form spores (Mazza *et al.*, 2006). This means, in *Streptomyces*, chromosome replication is independent of cell division but chromosome segregation and cell division are essential for proper spore formation. This is underlined by the role of *ftsZ*. Although dispensable for vegetative growth, *ftsZ* plays a crucial role in sporulation. In *S. coelicolor*, *ftsZ* possesses three promoters that allow a tightly controlled gene expression. The amount of FtsZ in aerial hyphae was found to be much higher than in vegetative filaments probably supporting the high number of septa necessary for spore formation.

1.1.4 Gram-negative spore formers

In contrast to the model Gram-positive spore formers, sporulation in Gram-negative bacteria is not well understood. Not only the overall cell envelope architecture of vegetative cells and, as far as known, of spores differs largely, but the whole process of spore formation is very different. Characterized spores of Gram-negative bacteria are resistant to desiccation, detergents, ultrasound and UV-radiation but they display less heat resistance than spores from Gram-positives (Whittenbury & Dow, 1977, Titus *et al.*, 1982).

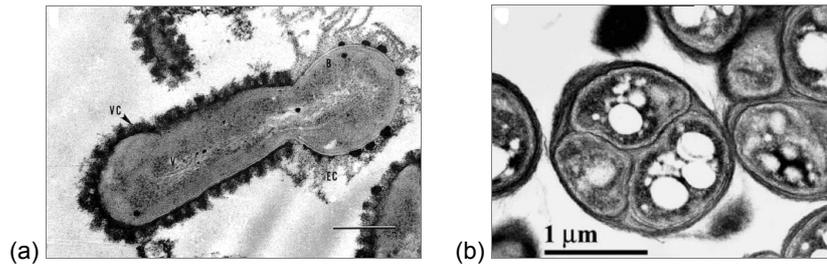

Figure 1-4 Electron micrographs of a spore-budding *Methylosinus* cell (a) (Titus *et al.*, 1982) and *Rhodospirillum* cysts (b) (Berleman & Bauer, 2004).

Spores from *Methylosinus* species (Alphaproteobacteria) are termed exospores. These entities are budded off from vegetative cells (**Figure 1-4 a**). Therefore, a cell-division event seems to be involved in exospore formation. In contrast, *Rhodospirillum* forms resting states termed cysts directly from vegetative cells, apparently circumventing cell division. Occasionally, few cysts can be enclosed in a common envelope (**Figure 1-4 b**). The nitrogen fixing genus *Azotobacter* (Gammaproteobacteria) has been studied in more detail. Desiccation-resistant cysts of these bacteria are enclosed by carbohydrate capsules that mainly consist of alginate. AlgU, an alternative sigma factor, plays an essential role in capsule formation and encystment (Gaona *et al.*, 2004). A common characteristic of Gram-negative resting cells seems to be accumulation of carbohydrates in the cell envelope (Sutherland & Mackenzie, 1977). However, the molecular mechanisms that enable vegetative cells to differentiate into resistant stages with large changes in morphology and metabolism are mainly unknown.

1.2 Spore formation in *Myxococcus xanthus*

1.2.1 Starvation-induced development

The most intriguing group of Gram-negative spore formers belongs to the Myxococcales order within the Deltaproteobacteria. Most known species within this order are characterized by a complex, multicellular lifecycle that culminates in formation of spherical myxospores (Kaiser, 2004). A model organism in this group is *Myxococcus xanthus*. The vegetative growing rod-shaped cells are common in soils and on decaying organic matter. They are able to move by gliding and form swarms that feed cooperatively on organic compounds or other microorganisms by secretion and pooling of lytic enzymes (Reichenbach, 1999). When nutrients are depleted, *M. xanthus*

swarms initiate an elaborate developmental program. Rod-shaped cells aggregate into mounds containing approximately 100,000 cells. The mounds compact into fruiting bodies and only the cells inside these fruiting bodies undergo distinct morphological changes, i.e. they differentiate into spherical, thick walled, resistant and metabolically quiescent spores. Non-aggregating cells form at least two more distinct subpopulations: Peripheral rods and cells that undergo programmed cell death. The latter fraction accounts for up to 90% of the entire population (Nariya & Inouye, 2008). The whole process of sporulation takes at least 72 hours. Mature myxospores are viable for several years (Harris & Singer, 1998). Upon sensing nutrient-rich conditions, spores germinate and re-enter the vegetative cycle (Figure 1-5).

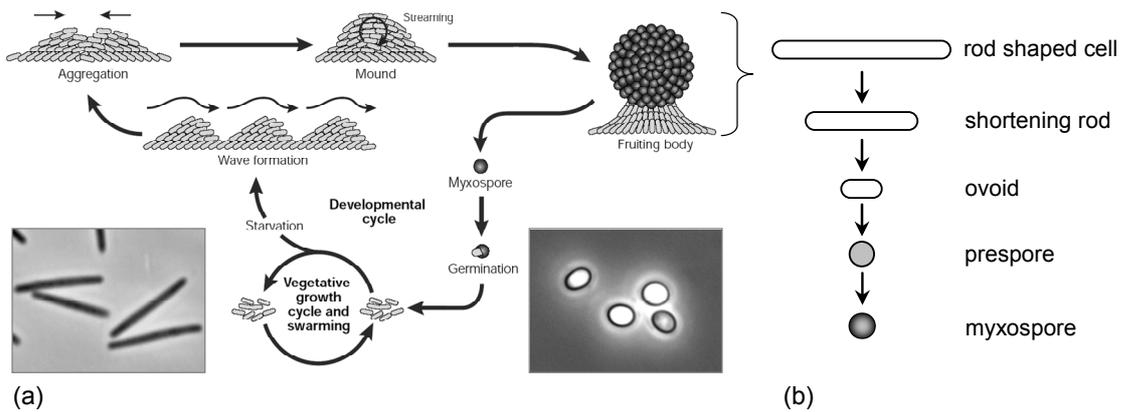

Figure 1-5 (a) Life cycle of *M. xanthus*. (taken from (Kaiser, 2003), modified). Phase contrast images of vegetative, rod-shaped *M. xanthus* cells and starvation-induced spores obtained from fruiting bodies illustrate the differentiation. (b) Schematic view of morphological changes during differentiation into myxospores that normally occurs inside fruiting bodies. Rod shaped cells shorten until they form ovoids and non-refractile spherical pre-spores. The pre-spores mature into resistant myxospores.

The starvation-induced developmental process is controlled by a series of intra- and intercellular signaling and temporal and spatially coordinated gene expression (Kaiser, 2004). A number of regulatory genes and enzymatic activities have been identified to play a crucial role during the starvation-induced development.

Current models (Søgaard-Andersen, 2004, Kaiser, 2004, Nariya & Inouye, 2008) suggest that the developmental program is initiated by sensing of nutrient limitation. Synthesis of (p)pGpp triggers A-signaling. The A-signal consists of specific amino acids and short peptides and is thought to serve as a quorum sensing messenger. Development only proceeds if a certain minimal population density is present (Plamann & Kaplan, 1999). The A-signal is probably perceived by SasS, a membrane bound histidine kinase that transduces the signal to SasR, its cognate response regulator. SasR is proposed to trigger expression of A-signal dependent genes (Kaiser, 2004) such as *mrpAB* and *C*. MrpC is a transcriptional regulator of the cyclic AMP receptor family. To activate downstream developmental genes, MrpC needs to be cleaved and its proteolytic product MrpC2 activates the key developmental transcriptional regulator gene, *fruA* (Nariya & Inouye, 2006) (Figure 1-6). *fruA* encodes for an orphan response regulator containing an N-terminal receiver and a C-terminal DNA binding domain. The

fruA-mutant is unable to aggregate (Ellehaug *et al.*, 1998, Horiuchi *et al.*, 2002, Ogawa *et al.*, 1996).

Activation of FruA by phosphorylation is thought to occur in response to the C-signal pathway (Ellehaug *et al.*, 1998). The C-signal is a 17 kDa cell surface exposed protein (p17) that is generated by proteolytic cleavage of its inactive precursor p25. p25 is encoded by *csgA* and synthesized in vegetative cells but up-regulated during starvation-induced development (Kruse *et al.*, 2001). The protein is essential for aggregation and fruiting body formation. It is exported to the cell surface by an as yet unidentified mechanism (Lobedanz & Sogaard-Andersen, 2003). Upon starvation, the cell surface anchored p25 becomes cleaved by PopC and thereby converted into its truncated active form (Rolbetzki *et al.*, 2008). By an unknown receptor, the 17 kDa protein of neighboring cells is recognized and the signal is transduced to the DNA-binding response regulator FruA (Sogaard-Andersen, 2004) leading to FruA-activation by phosphorylation.

The phosphorylated active FruA-protein is proposed to allow progression of development through a branched pathway (Sogaard-Andersen & Kaiser, 1996). One branch controls cell movement by methylation of the FrzCD methyl-accepting chemotaxis protein. Changes in FrzCD methylation during development diminishes the frequency of cell movement reversals and directs cells to aggregate into mounds (Zusman *et al.*, 2007). By a feed back loop, higher cell densities inside the mounds are thought to increase the contact dependent C-signaling and therefore phosphorylation of FruA.

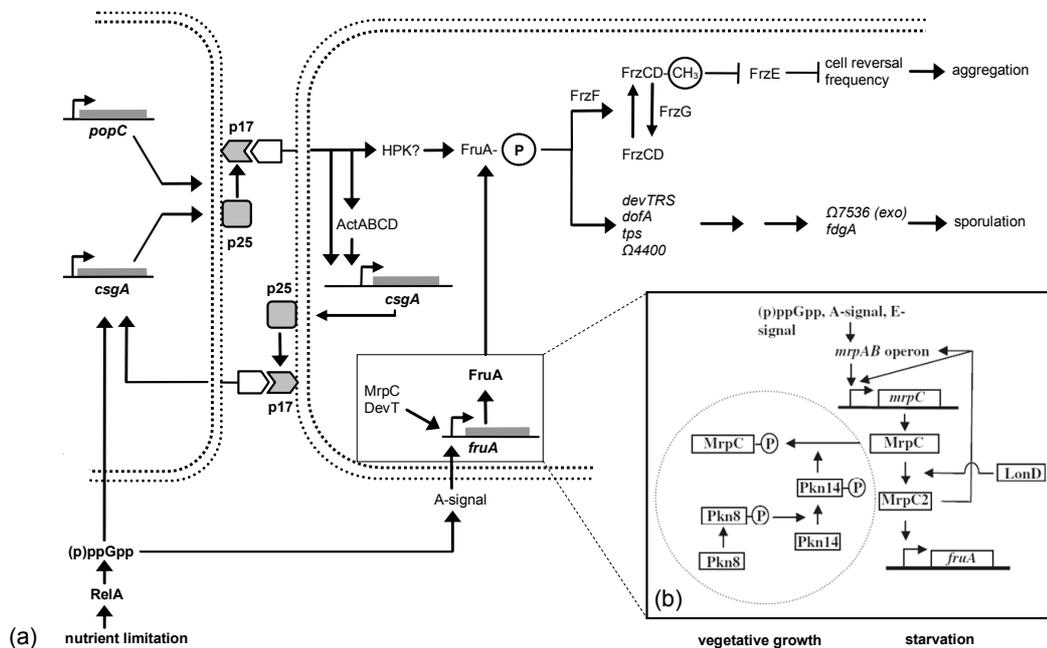

Figure 1-6 (a) Schematic view of proposed signal transduction pathways during *M. xanthus* starvation-induced development. The inset (b) depicts control of *fruA*-expression by MrpC2 in more detail (taken from (Sogaard-Andersen, 2008)), modified.

High levels of phosphorylated FruA are proposed to activate transcription of the *dev* locus inside the mounds (Viswanathan *et al.*, 2007) as part of the second branch. The *dev* genes are expressed inside fruiting bodies and are likely necessary for induction of sporulation (Thony-Meyer & Kaiser, 1993). Finally, late sporulation specific genes are expressed such as $\Omega 7536$ (*exo*). *exo* is essential to form mature spores (Licking *et al.*, 2000). The final stage of the sophisticated developmental program is the formation of resistant, spherical spores.

1.2.2 *M. xanthus* spores

Unlike in Gram-positive spore formers, *M. xanthus* spores are not formed by specific cell division processes nor by budding as in alphaproteobacterial species. Instead, an entire rod shaped cell converts into a spherical spore that matures and acquires resistance not inside a mother cell, but rather inside a multicellular fruiting body or, under certain circumstances, detached and freely. Myxospores do not possess the high resistance properties known from many Gram-positive spores. However, in contrast to vegetative cells, myxospores survive heat treatment up to 60°C and they are resistant to desiccation, UV-radiation, sonication and treatment with detergents such as SDS (Reichenbach, 1999, Sudo & Dworkin, 1969).

However, to examine the processes that developing *M. xanthus* cells undergo inside fruiting bodies has proven difficult. Genome wide transcriptional profiling, for example, is hampered by the fact that a developing culture divides into subpopulations with very different cellular fates. To identify genes involved in the late stage of spore formation is additionally hindered by the small proportion of emerging spores and by their high mechanical resistance.

Interestingly, a second means to rapidly generate spores is to add certain chemicals such as 0.5 M glycerol (Dworkin & Gibson, 1964), 0.7 M DMSO (Komano *et al.*, 1980), beta-lactam antibiotics, D-amino-acids (O'Connor & Zusman, 1997) and secondary alcohols (Dworkin & Gibson, 1964) to exponentially growing liquid cultures. The most effective inducers that have been identified are glycerol and DMSO (Komano *et al.*, 1980). In this case, resistant spores are formed within hours and virtually every cell converts into a resistant spore without forming fruiting bodies (Dworkin & Gibson, 1964). In contrast to starvation-induced sporulation, this process takes place in the presence of nutrients, is independent of cell density, it obviates the need of aggregation and most likely, no subpopulations are formed. Instead, it leads to a synchronized sporulating culture. However, glycerol- and starvation-induced spores are not identical as seen in electron microscopic images (**Figure 1-7**). The envelope layers of glycerol-induced spores are thinner and they contain apparently more ribosomes. Additionally, some spore specific proteins are detectable in starvation-induced, but not in glycerol-induced spores.

Importantly however, the two types of spores share many characteristics such as spherical shape, refractivity in phase contrast, and resistance to heat, sonication and detergents (Sudo & Dworkin, 1969) and both pathways induce a β -lactamase activity (O'Connor & Zusman, 1997).

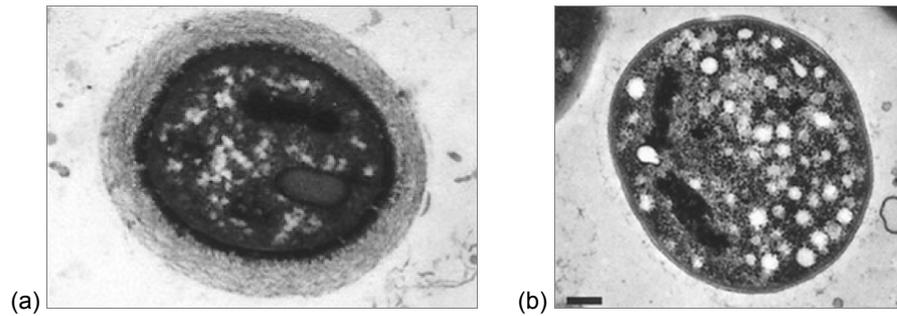

Figure 1-7 Electron micrographs of starvation-induced (a) and glycerol-induced (b) spores of *M. xanthus* (taken from (O'Connor & Zusman, 1999)).

Numerous proteins that are differentially expressed during *M. xanthus*' spore formation were found by early 1-D and 2-D SDS-PAGE approaches (Komano *et al.*, 1980, Inouye *et al.*, 1979b). However, most of these proteins have not been characterized except for few spore coat associated proteins. In particular, the spore coat proteins S and its homologue S1 have been studied in more detail. During starvation-induced development, synthesis of both proteins is differentially regulated. Protein S is synthesized soon after onset of starvation (Inouye *et al.*, 1979a), but protein S1 accumulates much later, when spores are formed (Downard & Zusman, 1985). Up to 15% of the total cellular protein synthesis during starvation-induced development is devoted to the early synthesized protein S (Komano *et al.*, 1980, Inouye *et al.*, 1979b) which is considered as the major spore coat protein. The mRNA of protein S has been shown to possess an unusually long half life of 15 to 30 minutes (Nelson & Zusman, 1983) which probably accounts for the high ratio of protein S synthesis. Protein S possesses the ability to self-assemble on starvation-induced spores (Inouye *et al.*, 1979a). However, it is yet unknown how the protein is exported from developing cells since the protein sequence lacks an obvious secretion signal. One model proposes that the protein first accumulates inside cells that have initiated the developmental program and is later set free by autolysis of non-sporulating cells. The free protein then may assemble on starvation-induced spores (Teintze *et al.*, 1985). The role of protein S is not yet clear since it seems not to be essential for spore resistance and viability (Komano *et al.*, 1984). A proposed function of this abundant protein is to mediate spore adhesion. Protein S is not detectable in glycerol-induced spores but its homologue and later synthesized protein S1 is detectable in both spore types (Downard & Zusman, 1985). Other spore-specific proteins that have been analyzed are protein U, W and C. Protein U is synthesized late during starvation-induced development and known from both starvation and glycerol-induced spores (Gollop *et al.*, 1991). Protein U is synthesized as signal-peptide containing precursor, secreted, and assembled on the spore surface. In contrast, protein W is detected only inside starvation-induced spores and is proposed to be involved in poly-phosphate storage (Otani *et al.*, 1998). Finally, protein C was shown to be early expressed during starvation-induced development and to be spore coat associated (McCleary *et al.*, 1991). Its sequence has not yet been published.

A recent 2-D gel proteomics approach has identified three more spore proteins (major spore proteins, MspA, B and C). Deletion of the according genes results in less resistant spores and structural defects (Dahl *et al.*, 2007). Furthermore, CbgA was identified to play a role in spore formation based on its homology to SpoVR, a *B. subtilis* protein that

is involved in the formation of the endospore cortex. The *cbgA* mutant also displays structural defects in the spore envelope and decreased spore resistance properties (Tengra *et al.*, 2006), and its fruiting bodies are of aberrant shape. However, the function of the proteins S, S1, U, C, the Msp's and CbgA has not yet been demonstrated.

Furthermore, some regulatory genes have been identified to cause a sporulation defect upon deletion. Inactivation of four of the *M. xanthus* NtrC-like activators (*nla4*, *6*, *18*, and *24*) leads to starvation and glycerol-induced sporulation defects (Caberoy *et al.*, 2003). Additionally, the alternative sigma factors B and C are involved in sporulation. Expression of the late stage sigma factor B starts at the onset of sporulation and only inside spores. The spores of the *sigB* mutant are viable but not stable. Therefore, SigB is proposed to be involved in spore maturation and maintenance of spore dormancy. Sigma factor C has been shown to be synthesized during sporulation but inactivation does not elicit an obvious sporulation defect. However, the *sigC* mutant forms fruiting bodies and spores on semi-rich media suggesting that SigC controls genes involved in repression of fruiting body formation in the presence of nutrients.

An interesting gene that has been identified by Tn5-*lacZ* insertion during starvation-induced development is *Mxan_3227* ($\Omega 7536$ or *exo*) (Licking *et al.*, 2000). *exo* stands for 'exopolysaccharide synthesis and export' and refers to its proposed function. The *exo*-gene is part of a cluster of nine genes consisting of four hypothetical genes, a putative tyrosine-kinase, an amino-transferase and three genes involved in carbohydrate metabolism and trafficking. Interestingly, the *exo*-mutant is blocked very late in starvation-induced spore formation. The mutant forms normal fruiting bodies but the cells inside are unable to finish shape conversion into spheres (**Figure 1-8**). Mature glycerol-induced spores are not formed suggesting that the *exo* gene is essential to form resistant, spherical spores, i.e. it is part of the core sporulation process. However, the function of this gene has also not been demonstrated. Interestingly, the same locus has been identified later again. Its first gene, *Mxan_3325*, is now termed *fdgA* (Ueki & Inouye, 2005). The *fdgA* mutant forms non-darkening fruiting bodies and spores with strongly reduced resistance but its glycerol spore-induction phenotype has not been reported.

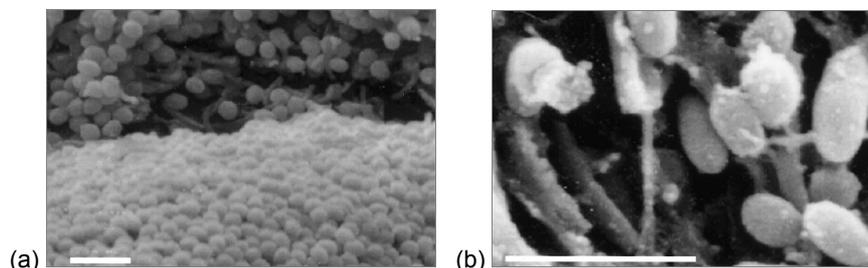

Figure 1-8 Scanning electron micrographs of starvation-induced wild type (DK1622) (a) and *exo* mutant (b) spores inside fruiting bodies (taken from (Licking *et al.*, 2000)).

In summary, the overall picture of spore formation in *M. xanthus* remains vague since the function of most spore-specific proteins has not been determined. Compared to the large regulons and signaling networks involved in *Bacillus*' spore formation, little is known about the processes in the Gram-negative *M. xanthus*.

Assays for specific enzyme activities suggest that upon spore formation, trehalose is synthesized and carbohydrate synthesis is activated (McBride & Zusman, 1989, Orlowski *et al.*, 1972). Intriguingly, a recent study demonstrated that glycerol spores do not contain peptidoglycan (Bui *et al.*, 2008). This is in sharp contrast to spores from Gram-positive bacteria and raises the question of what the *M. xanthus* spore envelope consists of. Besides the above mentioned spore coat proteins that only account for 14% of the spore coat dry weight and whose function is not yet clear, large amounts of glucose, galactosamine and glycine have been found (Kottel *et al.*, 1975). However, yet it is unknown how the carbohydrates become exported and assembled on the spores, if and how this material is cross-linked, and how it contributes to spore resistance. Deposition of the spore envelope material needs to be tightly controlled to avoid cell lysis during simultaneous peptidoglycan degradation. Additionally, the large structural changes in the spore envelope need to be tightly coordinated with the cell shape change process.

1.3 Cell shape control during spore formation and germination

One of the most interesting aspects of spore formation in bacilli is the shape transition from rod to sphere. As discussed previously, spore formation in *Bacillus* and *Streptomyces* arises from an unequal cell division. In case of *M. xanthus* however, the entire cell rounds up suggesting re-arrangements of cell wall and cytoskeleton. The cytoskeleton is largely the result of the actin-like MreB protein. This protein is highly conserved in most rod-shaped bacteria. It polymerizes into twisted filaments that are attached to the cytoplasmic membrane and traverse the longitudinal axis of the cell (Varley & Stewart, 1992, Figge *et al.*, 2004). It has been proposed that one task of the spiral-like MreB filaments is to indirectly position and to guide peptidoglycan synthases and lytic enzymes during growth (Figure 1-9) (Figge *et al.*, 2004) (Carballido-Lopez, 2006). By that means, the assembly of cell wall precursors occurs not at random positions but is highly coordinated and distinctly localized. Some related proteins have been shown to co-localize with the MreB filaments (Divakaruni *et al.*, 2005) but to date, besides RNA-polymerase and RodZ no direct interaction partners of MreB have been identified *in vivo* (Bendezu *et al.*, 2008, Kruse *et al.*, 2006).

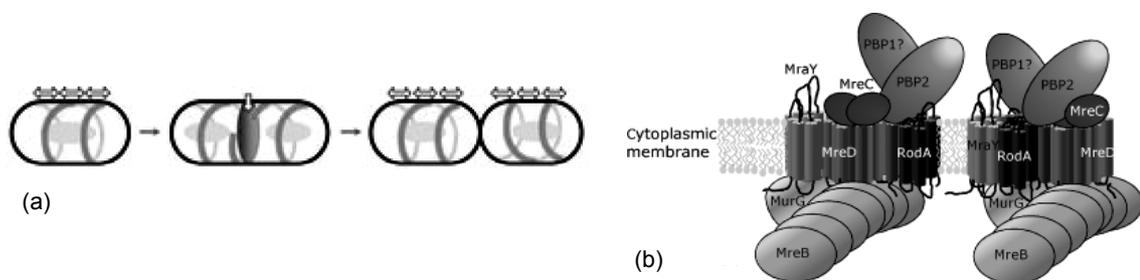

Figure 1-9 (a) Organization of MreB spirals in rod-shaped bacteria during vegetative growth and cell division (taken from (Carballido-Lopez, 2006)). (b) Proposed interaction partners of MreB forming the "elongase" complex, essential for lateral vegetative growth (from (den Blaauwen *et al.*, 2008)).

In the transition from vegetative cells to spores, *M. xanthus* must possess a means to regulate cell shape from rod to sphere and, during germination, back from sphere into rod. Therefore, the entire cell envelope needs to be extensively remodelled. A good candidate for regulation of this process is the structural protein, MreB. In various model organisms, such as *B. subtilis*, *C. crescentus* and *E. coli*, depletion of MreB turns the rod-like cells into spheres and repletion of the protein reconstitutes normal rod cell shape (Figge *et al.*, 2004, Carballido-Lopez & Formstone, 2007, den Blaauwen *et al.*, 2008). Additionally, MreB polymerization can be inhibited by addition of the chemical compound A22 (Iwai *et al.*, 2002b). In this case, existing MreB filaments are disassembled and rod-shaped cells turn also into spheres. Interestingly, in *E. coli*, inhibition of penicillin binding proteins (PBP's) involved in lateral cell wall growth, likewise leads to formation of spherical cells. Spiral-like MreB-filaments are still detectable in these spheres (Karczmarek *et al.*, 2007, den Blaauwen *et al.*, 2008). Therefore, different ways to form a sphere from a rod-shaped cell are possible. During shape change in *M. xanthus*, MreB may either be degraded or the MreB-filaments are disassembled to enable sphere formation. A third possibility is that the control of MreB on cell shape is interrupted by an unknown mechanism.

1.4 Scope

This thesis research focused on identification of not only single genes but whole clusters and functional groups likely to be involved in spore formation. This aim was approached by transcriptome profiling of a synchronized sporulating *M. xanthus* culture using micro arrays. The glycerol-induced spore formation process served as model for the spore formation process in general. The data set of significantly regulated genes was screened for both known and putatively novel core sporulation genes. Novel candidate genes were selected for more detailed analysis based on their ratio of up-regulation, their regulation pattern compared to known sporulation markers and their predicted subcellular localization. The role of a selected cluster of candidate genes in spore formation was analyzed by mutagenesis, genetic and biochemical approaches.

Simultaneously, the role of MreB during spore formation and germination was studied. Inhibition of MreB polymerization by A22 was investigated to analyze how *M. xanthus* accomplishes co-ordinated cell shape conversion.

2 RESULTS

2.1 Identification of the sporulation-specific transcriptome by micro array analysis

2.1.1 Genes significantly regulated in response to glycerol-induced spore formation

To identify genes involved in the *M. xanthus* sporulation process, micro array analysis was performed on a time course of cells sporulating in response to glycerol. The micro array chips used were provided by The Institute for Genomic Research (TIGR, <http://www.tigr.org/TIGRFAMs/>). Until the beginning of this work, this type of array had not been applied successfully. Thus, the experimental conditions had to be determined. The results of this optimization procedure are published (Müller & Jakobsen, 2008).

The arrays are based on the genome annotation from September 9, 2005 and comprise 7,200 of 7,380 *M. xanthus* protein coding sequences. Each sequence is represented by three spots of specific, identical 70-mers of single stranded DNA. Due to potential cross-hybridization, 472 of the sequences are termed 'not reliable' resulting in 6,728 reliable open reading frames (orfs) represented on the chips which accounts for approximately 91% of the *M. xanthus* protein coding sequences (B. Nierman, unpublished).

The time course experiment was carried out in three independent biological replicates. Samples were taken at 0.5, 1, 2, 4, 8 and 16 hours after addition of glycerol, processed as described in Materials and Methods (Section 4.8) and hybridized on the arrays together with samples from uninduced cells as reference (Figure 2-1). The tighter sample sequence at the beginning was chosen because major morphological and metabolic changes take place within the first four hours of induction (Sadler & Dworkin, 1966, Komano *et al.*, 1980, Orłowski *et al.*, 1972). After scanning and normalization, the data of each time course were pre-filtered applying an intensity criterion of signal minus background ≥ 100 in at least one channel and in at least one time point.

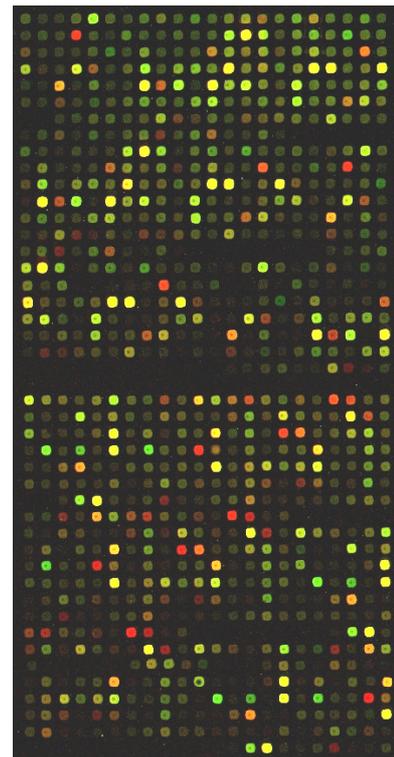

Figure 2-1 Representative section of a TIGR micro array displaying two blocks of spots. Hybridized are labeled cDNAs of vegetative cells (green) and cells that have been exposed to glycerol for 0.5 hours (red). Yellow color is the result of a red and green overlay and corresponds to genes that are expressed in both cell types.

These data were analyzed for significantly regulated genes by SAM (Statistical Analysis of Microarrays, Stanford University) applying a median false discovery rate (FDR) of 5%. A cut off criterion of two-fold up- or down-regulation was applied to this data set, resulting in 976 genes considered as significantly regulated above threshold. More detailed analysis of the array data revealed that from the eight hours time point on the number of detected regulated genes decreased. This phenomenon is probably not due to gene expression levels that drop below detection limits in sporulating cells, but was instead caused by the increasing resistance of the emerging spores. Spores at this stage do not lyse during the hot phenol RNA isolation method (data not shown) which resulted in loss of signals from some genes that were detected as up-regulated in the earlier time points. One of the applied quality criteria to call a gene significantly regulated was to only consider genes where data are present for each time point. Therefore, the samples until four hours were analyzed separately resulting in 1,596 significantly regulated genes (**Table 2-1**) which are listed together with their annotation in the Appendix (**Table A-15**).

Table 2-1 Numbers of regulated genes considering 4 hours and 16 hours time course (data present for all time points).

Time course	4 h	16 h
Significantly regulated genes	4,506	1,977
At least 2-fold up- or down-regulated genes	1,596	976

2.1.2 Previously described core sporulation genes are up-regulated

As a first step to analyze the micro array data, genes encoding for proteins known to be involved in the core sporulation process were searched. Genes that are obviously involved in other processes, such as motility or core metabolism, were not considered. For example, defects in motility can cause sporulation defects since cells are not able to form proper fruiting bodies. Likewise, mutations that interfere with parts of the central metabolism may evoke pleiotropic effects and also influence sporulation indirectly.

The known core sporulation related proteins were divided into groups. The first group contains structural proteins that have been detected specifically in the spore coat of either starvation- or glycerol-induced spores, or both. The second group contains regulatory proteins that have been shown to cause sporulation defects upon deletion. The third group contains metabolic enzymes whose activity has been shown to be highly increased during glycerol-induced sporulation and the fourth group contains proteins that are necessary to form resistant and viable starvation- or glycerol-induced spores but whose detailed function has not yet been characterized. **Table 2-2** lists these genes and the associated regulation in the microarray analysis.

The data suggest that 19 of the 26 listed sporulation marker genes are found to be up-regulated. Those that were not significantly regulated include the specifically in fruiting bodies expressed *devTRS* locus, tree transcriptional regulators (*nla4*, *18*, *24*), and the gene for protein W (*prW*), known to be not present in glycerol spores (**Table 2-2**).

Table 2-2 Known core sporulation process related genes.

G: glycerol spores, S: starvation spores, -: sporulation not affected, ?: unknown

^aInactivation affects glycerol sporulation (Müller & Higgs, unpublished).

^bNo increased enzyme activity in a non-inducible mutant.

^cViability defect after 12 days.

^d*sigB/sigC* double mutant may have a sporulation defect (Ueki & Inouye, 2001).

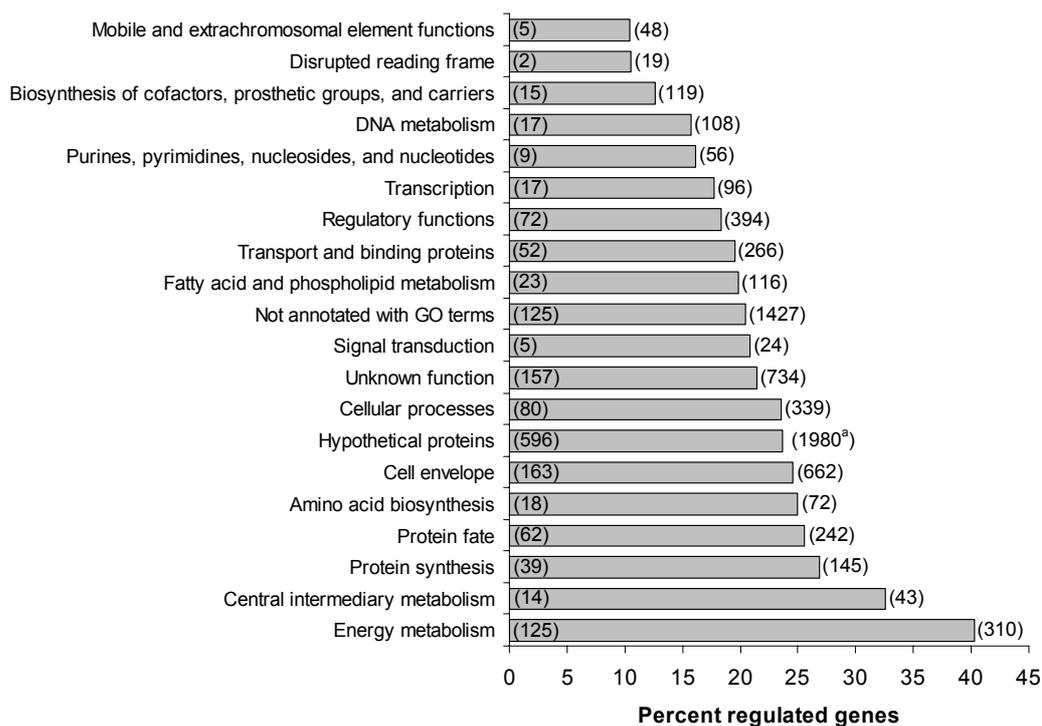

Figure 2-2 Percent of significantly regulated genes were sorted into the functional categories (bars) assigned by TIGR annotation. The functional categories are grouped based on their percentage of regulated genes. Numbers in brackets inside the bars indicate the regulated genes. The total number of genes in each category is indicated on the right. ^a1923 of the hypothetical proteins are also unannotated with gene ontology (GO) terms.

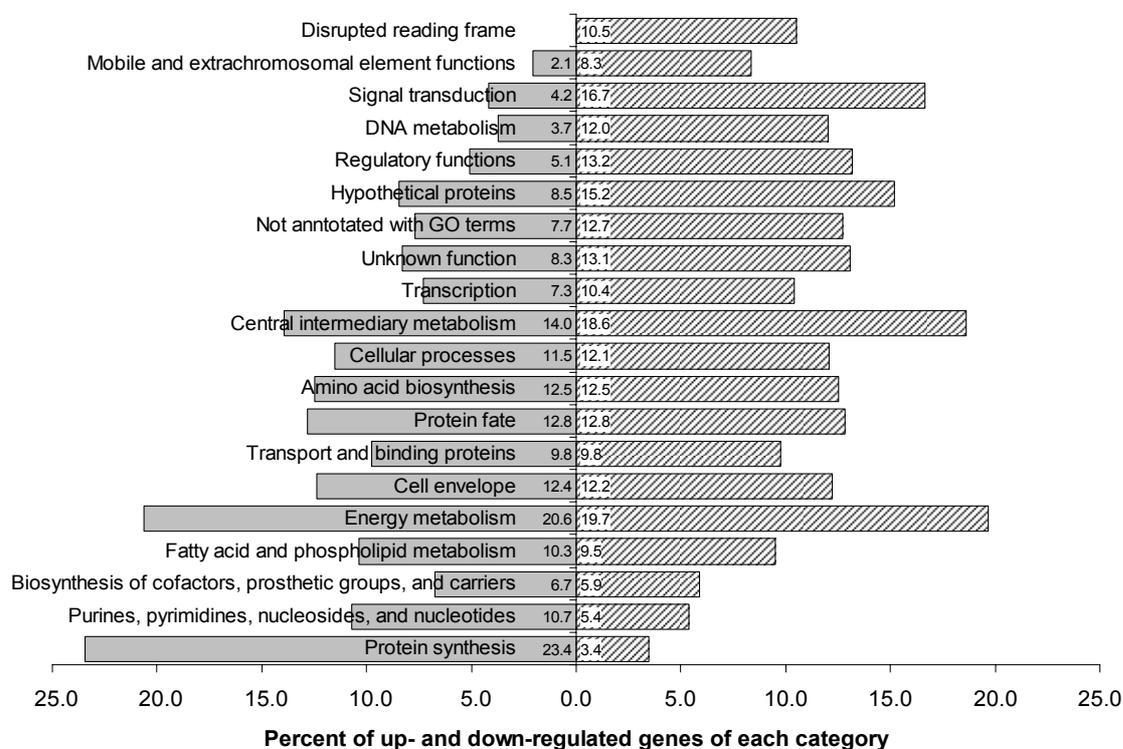

Figure 2-3 Proportions of up- and down-regulated genes in each functional category. Genes in each category were divided into up- (shaded) and down-regulated (gray) genes. The categories were sorted by the ratio of up- and down-regulated genes.

2.1.3 Functional categories

To determine whether the data are consistent with previous reports on sporulation genes and to study which cellular processes are most affected by glycerol induction, the regulated genes were first analyzed and grouped based on the genome annotation from TIGR that also assigns functional categories to most of the predicted gene products. For this purpose, the percentage of genes that change their expression level was calculated for each category (**Figure 2-2**). The data suggest that the major influenced functional groups are energy metabolism (40.3% genes of this category are either up- or down-regulated) and central intermediary metabolism (32.6%). Large changes in gene expression are also found in the categories protein synthesis (26.8%) and protein fate (25.6%).

To determine how the majority of genes in distinct categories are affected, the genes were further divided into up- and down-regulated genes (**Figure 2-3**). Interestingly, the proportion of up- and down-regulated genes is very different for distinct categories. More than 40% of all genes in the energy metabolism category change their expression level, but equal proportions are up- and down-regulated suggesting that the cells exchange large parts of their energy metabolism proteins. For example, all seven regulated genes for enzymes involved in glycolysis or gluconeogenesis are up-regulated as well as the genes for glyoxylate cycle enzymes whereas genes for seven TCA cycle associated enzymes are down-regulated. Down-regulated are also all six genes encoding for ATP-synthase subunits, twelve genes encoding cytochromes or cytochrome oxidase subunits and all ten genes encoding NADH dehydrogenase subunits consistent with the observation that respiration decreases by 80% during glycerol induction (Bacon *et al.*, 1975).

However, of the 26.8% regulated genes in the category protein synthesis, the vast majority are down-regulated including 28 genes encoding ribosomal proteins. This result is consistent with the observation that in glycerol-induced spores protein synthesis is reduced (Komano *et al.*, 1980, Sadler & Dworkin, 1966).

2.1.4 Grouping of the regulated genes by their expression profiles reveals distinct expression patterns

Co-regulated genes (regulons) are often involved in the same processes. The microarray technique allows monitoring expression levels of thousands of genes in parallel and is therefore particularly powerful to identify co-regulated genes (DeRisi *et al.*, 1997, Eisen *et al.*, 1998, Tavazoie *et al.*, 1999, Terai *et al.*, 2001). This approach can also provide information on processes in which novel genes might be involved.

To determine if all groups of core sporulation genes (**Table 2-2**) share the same expression profile or if there exist distinct patterns for specific groups, the significantly regulated genes were analyzed for genes with similar expression profiles. **Figure 2-4 a** displays a heat map where the genes are sorted by their regulation at 0.5 hours after addition of glycerol. As indicated by the intense yellow color, the genes at top of the map are highly expressed at the beginning of the experiment. However, their expression levels decrease towards the end of the time course as emphasized by the upper bracket.

The map also suggests that there exists a second group of highly expressed genes but with peak expression levels at two to four hours (lower bracket).

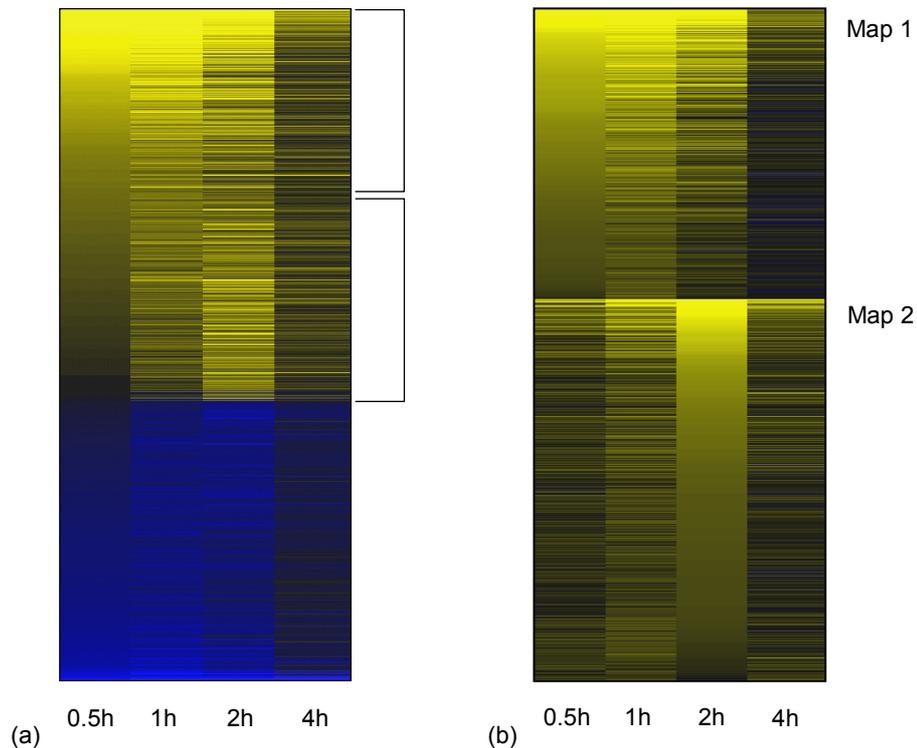

Figure 2-4 Heat maps of significantly regulated genes. Each column corresponds to one time point and each row corresponds to one regulated gene. Yellow colour indicates up-regulation, blue indicates down-regulation. The colour intensity matches the magnitude of regulation compared to uninduced cells. (a) The genes are sorted by their expression levels at 0.5 hours. (b) The set of up-regulated genes was grouped into two maps by hierarchical clustering resulting in one map containing early peaking genes (Map 1) and in one map containing later peaking genes (Map 2). The genes are sorted by expression levels at 0.5 and 2 hours.

To verify that the genes follow different regulation patterns, hierarchical clustering was applied to group the genes according to their specific expression profiles. Additionally, for this analysis only genes were considered that are up-regulated in at least one time point. These analyses revealed that the array data fit best if divided into two groups (**Figure 2-4 b**).

The previously described sporulation marker genes (**Table 2-2**) were then analyzed for their placement in the first or second set of up-regulated genes. The genes for the spore coat associated proteins S, S1 and U are found in Map 2. However, *actA*, *nla6*, *fdgA*, $\Omega7536$ (*exo*), *mshA*, *cbgA*, *Mxan_1101* and *Mxan_3026* cluster in Map 1. Interestingly, inactivation of the former genes for spore coat proteins does not affect spore viability, but deletion of the latter sporulation markers in Map 1 interferes with glycerol-induced and/or starvation-induced sporulation. These results suggest that the array data can be organized into groups to enrich for essential sporulation genes.

2.1.5 Real time PCR on sporulation marker genes confirms the array-based regulation patterns

To confirm the regulation patterns determined by micro array analysis, real time PCR analysis on selected genes was performed. For this study, highly up-regulated as well as some known sporulation marker genes were selected. Additionally, the expression pattern of one down-regulated gene was analyzed. Sigma factors B (*sigB*) and C (*sigB*) are examples for highly transcribed regulatory genes, *atpE* and *devR* are examples for weakly or unregulated genes. *Mxan_5543* was chosen to represent down-regulated genes. *mspC*, *prU* and $\Omega 7536$ (*exo*) are highly activated sporulation markers.

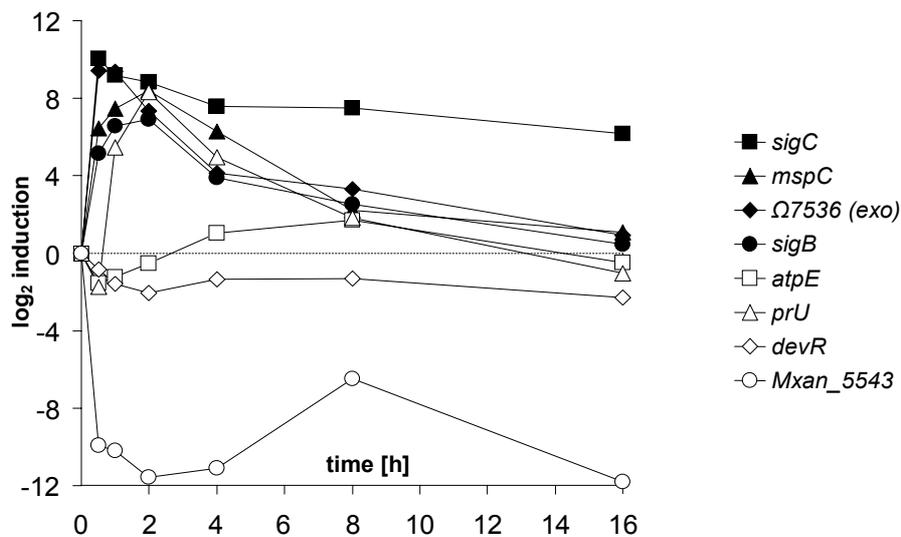

Figure 2-5 Real time PCR analysis of representative genes. Primers specific for *sigC*, *mspC*, $\Omega 7536$ (*exo*), *sigB*, *atpE*, *prU*, *devR* and *Mxan_5543* were used to amplify cDNA templates generated from RNA used in the microarray experiments.

Table 2-3 Comparison of maximum fold induction rates of marker genes.

Gene	<i>sigC</i>	<i>mspC</i>	$\Omega 7536$ (<i>exo</i>)	<i>sigB</i>	<i>atpE</i>	<i>prU</i>	<i>devR</i>	<i>Mxan_5543</i>
Fold induction								
Micro array	140.5	203	57.4	50.5	-3.7	93.5	-	-154.2
Real time PCR	1058.9	340.5	676.9	119.7	-2.9	322.2	-4.9	-3535.2

The array-based regulation patterns as well as the time points of peak expression / repression are confirmed by real time PCR analysis. The only exception is *sigC* which was placed in the group of later peaking genes (**Figure 2-4 b**). Real time PCR suggests that expression of this gene is highest at 0.5 hours (**Figure 2-5**). However, the changes in *sigC* expression are only minor as this gene stays highly activated during the whole time course. The differences in the calculated fold-changes between array and real time PCR are due to characteristics of the different methods such as the much higher sensitivity of the amplification-based PCR (**Table 2-3**).

2.1.6 Insertion mutagenesis in several up-regulated loci generated mutants defective in glycerol-induced sporulation

One approach to identify genes essential for spore formation is to inactivate candidate genes by insertion mutagenesis. Most of the known sporulation marker genes were found to be up-regulated. However, these genes belong to different gene ontology categories. To study if the up-regulated genes of different categories contain additional putative uncharacterized sporulation genes, the data were screened for up-regulated genes in different categories that could also be involved in spore formation. In this study, 14 open reading frames were selected for inactivation. Eight are predicted to reside in an operon such that inactivation of these genes likely causes polar effects.

Nine of the mutants displayed no obvious glycerol sporulation defect; three mutants could not be obtained suggesting that the genes are essential. Two mutants were deficient in glycerol spore formation (**Table 2-4**).

Both mutants defective in glycerol sporulation are affected in genes that are up-regulated highly and immediately. Additionally, the predicted gene products of *Mxan_1101* and *Mxan_3026* are probably involved in cell envelope modifications during sporulation. This suggests that these properties provide reasonable criteria to select additional candidates for mutagenesis.

2.1.7 Identification of the *nfs* locus

The simultaneous second approach was to search for genes likely to be involved in spore formation based on the following criteria:

Criterion #1: ≥ 16 -fold up-regulation

High up-regulation suggests that the according gene products are important for conversion of vegetative cells into spores. Notably, genes for synthesis, modification and export of abundant structural proteins are expected to be highly activated. Applying this criterion yielded 122 candidate genes.

Criterion # 2: *Predicted to localize to the cell envelope*

Major changes during spore formation involve the cell envelope. In contrast to vegetative cells, spores contain an enhanced, resistant envelope with an electron dense cortex and a prominent protein layer (Rosenbluh & Rosenberg, 1989, Kottel *et al.*, 1975, Dahl *et al.*, 2007). Additionally, the cell shape itself is altered suggesting changes in cell wall synthesis and composition. Moreover, sporulation mutants either display spore envelope defects (such as *mshA* and *mshC*) or the according proteins are predicted to localize or to act in the cell envelope (such as Ω 7536 (*exo*), *fdgA* and the two newly identified genes from this study *Mxan_1101* and *Mxan_3026*).

Table 2-4 Loci selected for insertion mutagenesis.

Name ^a	Annotation	Map	Max. log induction	In putative operon	Glycerol spore formation affected
<i>Mxan_0110</i>	Fatty acid synthase	1	10.6	No	No mutant
<i>Mxan_0434</i>	Glycogen debranching enzyme	1	12.1	Yes	No
<i>Mxan_0433</i>	Hypothetical protein	1	2.5		
<i>Mxan_0524</i>	Response regulator	1	30.0	Yes	No
<i>Mxan_0525</i>	Serine/threonine protein kinase	2	2.5		
<i>Mxan_0526</i>	Hypothetical protein	1	43.4		
<i>Mxan_0527</i>	Efflux transporter	1	15.1

<i>Mxan_1102</i>	RNA modifying enzyme		7.4		
<i>Mxan_3026</i>	O-antigen polymerase	1	22.7	Yes	Yes
<i>Mxan_3027</i>	Glycosyltransferase	1	97.8		

^aGenes in bold were selected as targets for insertion mutagenesis. Genes putatively influenced by polar effects are following.

The subcellular localization of the selected candidate genes was predicted by CELLO (Yu *et al.*, 2004). Only genes for proteins with predicted cell envelope localization (cytoplasmic membrane, periplasm or outer membrane) were considered. Applying this criterion left 41 candidate genes.

Criterion # 3: *The role of the gene products is not yet characterized.*

Since spore formation in *M. xanthus* is unique compared to other bacteria, it is likely that proteins without characterized homologues are involved. For that reason, hypothetical or conserved hypothetical proteins that fit the two above criteria were searched leading to a set of 20 candidate genes.

By this means, a genomic region consisting of consecutive genes was identified. As shown below, this gene cluster is one of the most intriguing loci identified and will subsequently be termed *nfs* (*n*ecessary *f*or *s*porulation).

2.1.8 The *nfs* locus consists of eight consecutive, highly up-regulated genes that cluster in Map 1.

The genes of the *nfs* locus are highly up-regulated. According to microarray data, the first gene *Mxan_3371* is the highest up-regulated gene at 0.5 hours (150-fold) and the following seven genes (*Mxan_3372* - *Mxan_3378*) belong to the 50 highest activated genes in this group (Table 2-5). Additionally, all *nfs* genes are activated early and cluster in Map 1 (Figure 2-4 b) together with *actA*, *fdgA*, $\Omega 7536$ (*exo*), *mSPA*, *cbgA*, *Mxan_1101* and *Mxan_3026* which cause sporulation defects when mutated (Table 2-2).

The locus consists of eight predicted genes (*Mxan_3371* – *Mxan_3378*) oriented in the same direction (Figure 2-6).

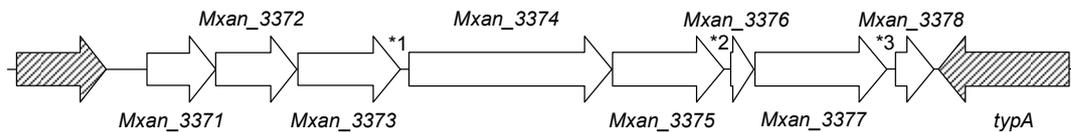

Figure 2-6 Genetic organization of the *nfs* locus. Arrows represent each predicted gene; stars indicate intergenic regions of *1: 163, *2: 201 and *3: 152 bp.

Table 2-5 Maximum fold up-regulation of the eight *nfs* genes determined by micro array analysis.

Gene (<i>Mxan_</i>)	3371	3372	3373	3374	3375	3376	3377	3378
Fold up-regulation	153	17	78	55	51	87	64	36

The gene *Mxan_3370* upstream of *nfs* is oriented in the same direction and annotated as protein of the large ribosomal subunit (*rplC*). The *nfs* locus is separated from *rplC* by 323 bp non-coding sequence. *rplC* is not significantly regulated as shown by micro array analysis and real time PCR (Figure 2-9 a). The gene downstream of *nfs* (*Mxan_3379*) is annotated as *typA*, a GTP-binding translational regulator. This gene is also not significantly regulated and is oriented in the opposite direction. Therefore, both flanking genes are not part of the *nfs* locus.

2.1.9 The *nfs* locus encodes for proteins with uncharacterized functions

All eight Nfs proteins are annotated as hypothetical or conserved hypothetical which means that they do not contain any catalytic domains of known function. Therefore, the predicted sequences were analyzed by bioinformatics tools in detail to gain information about their probable subcellular localization, possible protein interactions and distribution in other species. Several structural domains were found in the *nfs* proteins. A survey of the results is outlined below.

Table 2-6 Predicted subcellular localization of the Nfs proteins.

Protein	Prediction algorithm/server			
	CELLO ^a	PSORTb ^b	Phobius ^c	Subloc ^d
NfsA	Outer membrane/ Cytoplasm/Periplasm	Outer membrane	Non-cytoplasmic	Cytoplasmic (63%)

NfsE	+	+ ^a	+	+
NfsF	+	+	+	+
NfsG	-	-	-	-
NfsH	+	+	+	+

^aPeptide is predicted to be signal protease II cleavable suggesting that the protein is anchored to the membrane by a lipid modification.

Subcellular localization prediction programs suggest that the Nfs proteins are non-cytoplasmic. The CELLO-predictions are supported by results of PSORTb and Subloc where highest scores are found for predicted periplasmic or outer membrane localization (Table 2-6). Export of proteins from the cytoplasm is often mediated by N-terminal signal peptides and membrane localization can be determined by structural motifs such as hydrophobic transmembrane domains, lipid modifications or beta barrel folds. For that reason, the protein sequences were screened for signal peptides and additional structural domains (Table 2-7 and Table 2-8).

Table 2-8 Predicted structural motifs in the Nfs proteins.

Protein	COG-Domains ^c	Pfam-motifs	3D-structures	Catalytic domains	Post-translational modification sites

^edetected by Phyre (protein 3D modeling) (Bennett-Lovsey *et al.*, 2008)

^ffurther domains were aligned based on TPR motifs

The results suggest that at least five of the eight Nsf proteins possess signal peptides and are exported from the cytoplasm. For NfsA and H there are predictions for beta-barrel structures which suggests that these proteins reside in the outer membrane. NfsD may be attached to the inner membrane via a transmembrane domain and NfsE is predicted to be membrane anchored by a lipid modification. The remaining proteins NfsB, C, F and G do not possess a predicted membrane attachment structure. However, besides NfsG they all possess signal peptides.

NfsD and E contain multiple tetratricopeptide repeat (TPR) domains; NfsG contains a putative fork head-associated (FHA) domain. TPR domains are abundant motifs in several proteins and mediate molecular recognition in protein interactions (D'Andrea & Regan, 2003). FHA domains bind phospho-threonine containing proteins (Durocher *et al.*, 2000) and also predicted to be involved in protein interactions.

Blast searches against to date available annotated bacterial genomes revealed that some of the Nfs proteins have homologues in other bacteria. Notably, the entire locus seems to be conserved in the closely related species *Stigmatella aurantiaca* (Stiau2471 - 78) suggesting that the Nfs proteins provide functions not only restricted to *M. xanthus*. In particular, *S. aurantiaca* is able to form spores as *M. xanthus*. *Sorangium cellulosum* and *Bdellovibrio bacterivorus* are more distantly related species but both are able to form spores or cysts (Qualls *et al.*, 1978, Tudor & Conti, 1977b, Tudor & Conti, 1977a, Vasquez *et al.*, 1985). Moreover, there exist paralogues in *M. xanthus* itself (Table 2-9). However, these proteins seem to have different functions since the respective genes are not up-regulated in the micro array studies. NfsC, D and G have homologues in other Deltaproteobacteria. The high number of related sequences for NfsD, E and G in species of other phyla is probably due to the presence of TPR repeats in NfsD and E and the FHA-domain in NfsG.

Table 2-9 Distribution of Nfs homologues in other bacterial species. The protein sequences were analyzed with the FastBlast algorithm (E-value below 0.003) of Microbesonline (Alm *et al.*, 2005) containing 747 bacterial genomes.

Protein	<i>M. xanthus</i>	<i>S. aurantiaca</i>	<i>A. dehalogenans</i>	<i>B. bacterivorus</i>	<i>S. cellulosum</i>	Other Deltaproteobacteria	Other phyla
NfsA	-	1	-	-	-	-	-

NfsH	-	1	-	-	-	-	-

2.1.10 Analysis of functional predictions

As mentioned above, except for NfsC there are no predictions for catalytic activity or a structural role for the Nfs proteins. However, iterative PsiBlastp analysis can be applied to find proteins with similar partial sequence architecture and distantly related proteins or new members of a protein family (Altschul *et al.*, 1997). This analysis was used to gain more information about the processes in which the proteins might be involved.

Table 2-10 Position specific iteration Blastp results. Only proteins with known or predicted function / localization that were aligned more than once are shown.

Protein	Putative function	No. of aligned sequences
NfsA	OmpW/OmpA related outer membrane protein, porin	>300
NfsB	Cell surface or secreted protein / Glucan binding	>100 ^b
NfsC	Glycosyltransferase	6
	O-linked N-acetylglucosamintransferase	6
	Prenyltransferase	2
NfsD	Glycosyltransferase	5
	Glucosamintransferase	6
	TPR-repeat containing proteins of unknown function	>400
NfsE	Glycosyltransferase	5
	O-linked N-acetylglucosamintransferase	9
	Sulfotransferase	10
NfsF	-	-
NfsG	ABC-transporter / Efflux pump	>100
	Sigma54 dependent responseregulator	>40
	Adenylate / Guanylatecyclase	>20
NfsH	OmpA-related outer membrane protein, porin	>100
	OmpW related outer membrane protein, channel ^a , stress response	>20
	OprF, porin	>20

^a(Hong *et al.*, 2006)

^bafter five iterations, inconclusive results after ten iterations

PsiBlastp iterations were run with a maximum of 500 sequences against all bacterial non-redundant GenBank CDS translations including PDB (Protein Data Bank), SwissProt, PIR (Protein Information Resource) and PRF (Protein Research Foundation) excluding environmental samples from WGS (Whole Genome Shotgun Submission) projects. Sequences were included with an E-value threshold below 0.005. After two to three iteration steps, hypothetical or conserved hypothetical proteins of Myxobacteria and other bacterial species were aligned. Further iterations also raised protein sequences with predicted function for most of the Nfs proteins and after nine to ten steps no new sequences were found indicating saturation of the alignments. Exceptions are the small proteins NfsF and H. For NfsF, saturation with hypothetical protein sequences was

observed after five iterations and for NfsH after four iterations. In case of NfsH, increasing of the cut-off E-value for new detected sequences led to rapid alignment of OmpA/OmpW-related outer membrane proteins. Due to TPR motifs in NsfD and E, PsiBlastp searches were also carried out with truncated sequences lacking the TPR motifs to avoid artificial selection for TPR-related sequences. Nevertheless, the algorithm aligned mainly TPR motif-containing sequences to the truncated versions.

2.2 The *nfs* locus is necessary for sporulation

To determine if the *nfs* genes are necessary for the core sporulation process, a Δnfs mutant was generated. The markerless in-frame deletion of all eight genes (12.5 kb) was accomplished by fusion of the six 5'-terminal codons of *nfsA* to the six 3'-terminal codons of *nfsH*. A schematic overview of the in-frame deletion procedure is shown in Materials and Methods (**Section 4.4.4**).

The Δnfs strain was analyzed for its ability to form both glycerol- and starvation-induced spores.

2.2.1 The Δnfs mutant does not form glycerol-induced spores

To study if the Δnfs mutant is impaired in glycerol spore formation, liquid cultures of both wild type and Δnfs mutant were induced with glycerol for 24 hours and assayed for the formation of heat and sonication resistant spores. After heat and sonication, no spores of the mutant were observed by phase contrast microscopy. The treated samples were also plated and allowed to form colonies for seven days. The results indicate that the Δnfs mutant is not able to form resistant glycerol-induced spores suggesting that the *nfs* genes are indeed involved in the sporulation process (**Table 2-11**).

Table 2-11 Viability of glycerol-induced spores in wild type and Δnfs strain. Equivalent cell numbers induced with glycerol were treated with heat and sonication and then plated on rich media. Values are recorded as percent of wild type (wt) cfu.

Strain	Sporulation efficiency [% of wt]	Spore viability [% of wt]
wt (DK1622)	100	100
Δnfs	0	0.001

2.2.2 Δnfs displays aberrant cell morphologies upon glycerol induction

To analyze the sporulation defect in more detail, a time course experiment was carried out where Δnfs and wild type cells were induced with glycerol and imaged at distinct time points. Up to four hours after induction, no differences were visible (**Figure 2-7**). Both strains started to shorten and to form ovoids and spheres. After eight hours, wild type cells were mostly spherical and bright in phase contrast suggesting dehydration and acquisition of an enhanced cell envelope. However, Δnfs cells failed to turn bright in phase contrast. Instead, the translucent cells started to gain in size and after approximately twelve hours, the cells converted back into rods. During this process, a

transient malformed, spiral like cell morphology was visible. After an additional six hours of incubation, all Δnfs cells showed a normal rod shape even in the presence of glycerol.

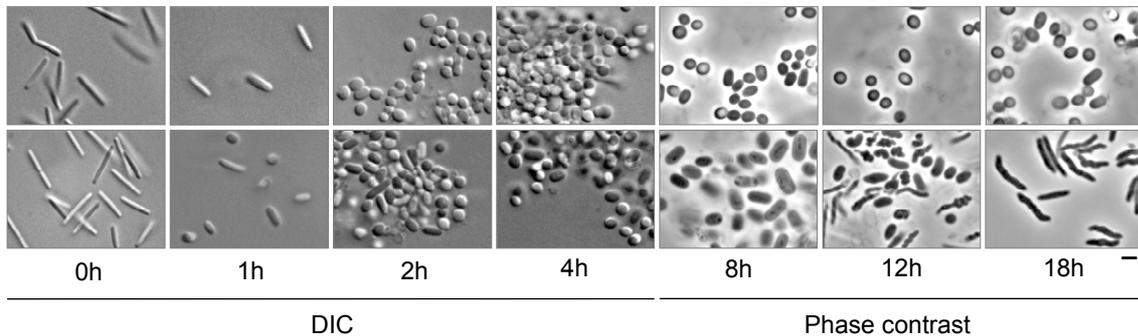

Figure 2-7 Time course analysis of glycerol-induced spore formation. Wild type (upper panel) and Δnfs (lower panel) were induced with glycerol and imaged at the indicated time points at 1000-fold magnification. After eight hours, cells were imaged with phase contrast to better visualize the differences between wild type and Δnfs . Bar: 1 μ m.

2.2.3 Δnfs forms fruiting bodies but less resistant starvation-induced spores

To determine if the *nfs* genes are necessary for starvation-induced development, the Δnfs mutant was tested for its ability to form fruiting bodies and resistant spores under several nutrient limited conditions.

Analysis of starvation-induced development indicated that the Δnfs mutant behaved as wild type with respect to timing and morphology of aggregation centers under submerged culture conditions (**Figure 2-8 a**), on CF nutrient limited plates (**Figure 2-8 b**) and on TPM strict starvation plates (data not shown). However, while wild type aggregation centres darken after approximately 48 hours development, Δnfs failed to darken even after 120 hours (**Figure 2-8**) suggesting that spores of the deletion strain do not mature (Morrison & Zusman, 1979).

To determine if spores can be isolated from the mutant, cultures were harvested after 120 hours, and heat and sonication resistant spores were enumerated using a counting chamber. Surprisingly, in submerged culture, equal numbers of heat and sonication resistant spores could be isolated from the Δnfs mutant as from wild type (**Table 2-12**). However, these spores were not refractile (**Figure 2-8 a**) and unable to germinate efficiently (only 2.6% of wild type \pm 16%). Cells grown on CF produced fewer heat and sonication resistant spores (28.2% of wild type \pm 15%) that also failed to germinate. The results suggest that the Δnfs mutant does not have a defect in aggregation and timing of development but in formation of viable spores.

Table 2-12 Efficiency and viability of starvation-induced spores in wild type and Δnfs strain. Numbers are recorded as percent of wild type.

Condition	Strain	Sporulation efficiency [% of wt]	Spore viability [% of wt]
Submerged	wt (DK1622)	100 ± 7	100 ± 16
	Δnfs	103.3 ± 12	2.6 ± 16
CF	wt (DK1622)	100 ± 12	100 ± 30
	Δnfs	28.2 ± 16	5.4 ± 35

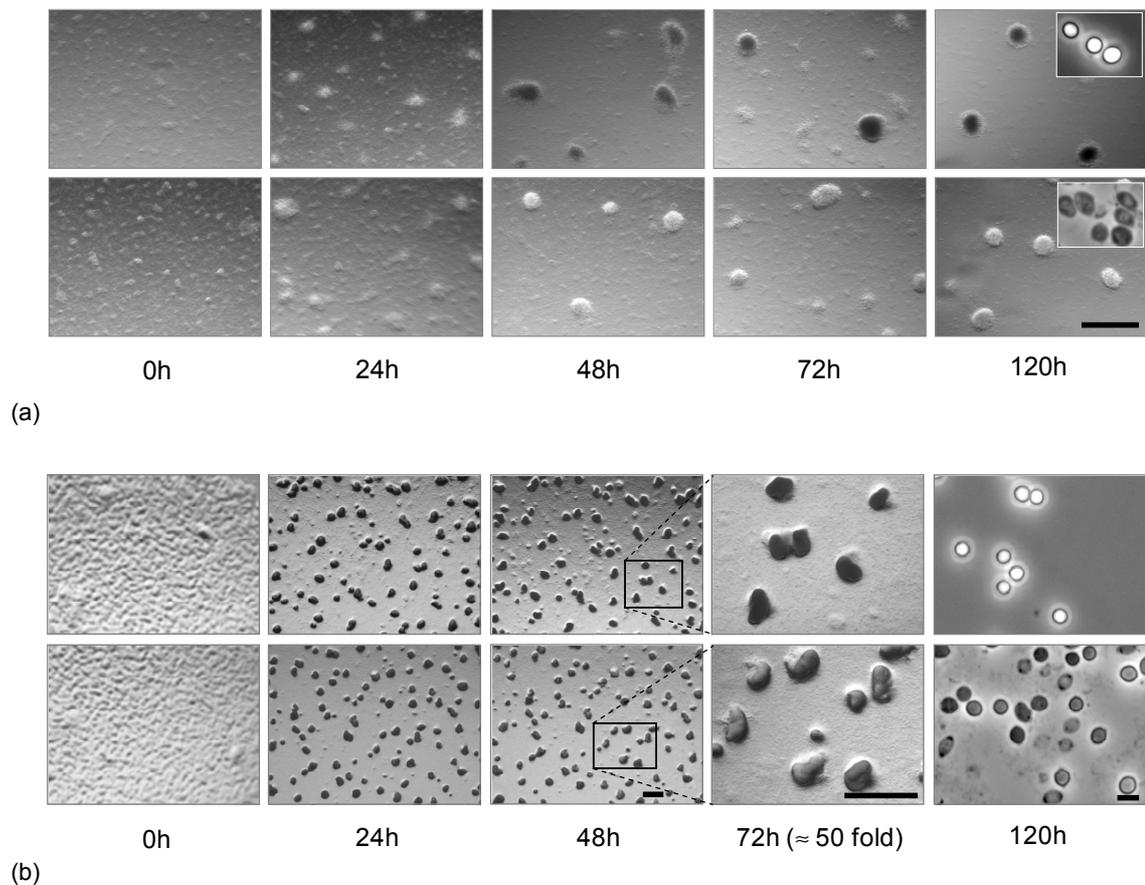

Figure 2-8 Stereo microscope and phase contrast images of wild type and Δnfs developed for five days. (a) Submerged culture. Bar: 1 mm. Insets: Phase contrast micrographs of isolated spores. (b) CF agar. Bar: 0.5 mm. Last images in each row are phase contrast micrographs. Bar: 1 μ m.

2.3 The *nfs* locus becomes activated when rod-shaped cells convert into spheres

To characterize the *nfs* locus in more detail, we confirmed the *nfs* gene expression pattern during glycerol induction, and examined the pattern during a developmental time course.

2.3.1 *nfs* gene expression and protein accumulation during glycerol-induced sporulation

To confirm the *nfs* expression pattern observed in the microarray analysis, the cDNA from a glycerol-induced time course was tested by real time PCR. Consistent with the micro array data, *nfsA*, *D* and *H* as well as $\Omega 7536$ (*exo*) were highly up-regulated at 0.5 to two hours and *Mxan_3370* (*rplC*) upstream of *nfs* appears to be not regulated (**Figure 2-9 a**).

To determine the pattern of protein accumulation, the glycerol-induced cultures were next examined by immunoblot analysis using anti peptide antibodies (Eurogentec) generated against NfsA to H (**Figure 2-9 b**). The apparent molecular masses of the Nfs proteins approximately matched the predicted masses (**Table 2-13**).

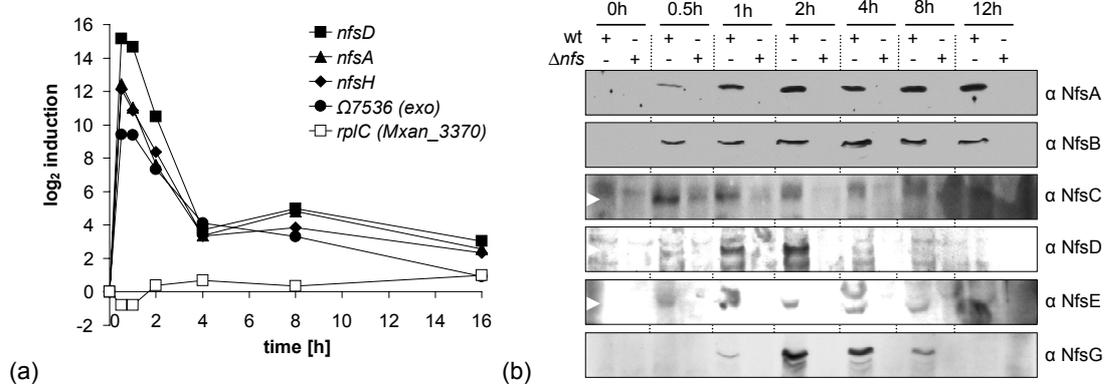

Figure 2-9 *nfs* gene expression and protein accumulation. (a) Real time PCR analysis on three selected *nfs* genes. $\Omega 7536$ (*exo*) was used as a highly up-regulated sporulation marker gene. The expression profile of *Mxan_3370* (upstream of the *nfs* locus) was also determined. (b) Anti-Nfs immunoblots on protein samples from glycerol-induced cultures. Equal culture proportions were harvested at the indicated times after induction with glycerol, proteins were released by bead beating, resolved by SDS-PAGE, and probed with anti-sera specific to NfsA - H.

Table 2-13 Number of amino acids, calculated and observed molecular weight of the Nfs proteins.

Protein	Amino acids	Calculated molecular mass [kDa]	Apparent molecular mass (SDS-PAGE) [kDa]
NfsA	294	32.3	30
NfsB	442	47	53
NfsC	512	57.5	57
NfsD	1219	137	140
NfsE	499	52	55
NfsF	96	10.8	-
NfsG	682	70.4	73
NfsH	200	21.3	-

Antibodies against NfsF and NfsH failed to recognize a specific protein in cell lysates (data not shown). NfsA, B, C, D, E, and G could not be detected in vegetative cells but

started to accumulate 0.5 hours after induction with glycerol. Interestingly, however, while NfsA, B and C were stably accumulated from 0.5 to twelve hours, accumulation of NfsD, E and G began to reduce after two hours and the proteins were absent after eight hours. Since the mRNA transcription profiles of all eight *nfs* genes are very similar, this may reflect differences in protein stability controlled by proteolysis.

As shown above, the *nfs* genes are immediately up-regulated during glycerol induction. To see if every cell activates expression of the *nfs* locus, a fusion of the putative *nfs* promoter region with *mcherry* was generated and the vector introduced into the Mx8 phage attachment site of *M. xanthus* DK1622. As control strain, *mcherry* was also fused to the *pilA*-promoter in order to express the reporter constitutively while the wild type bearing the empty vector served as negative control. The strains were induced with glycerol and imaged by fluorescence microscopy (**Figure 2-10**).

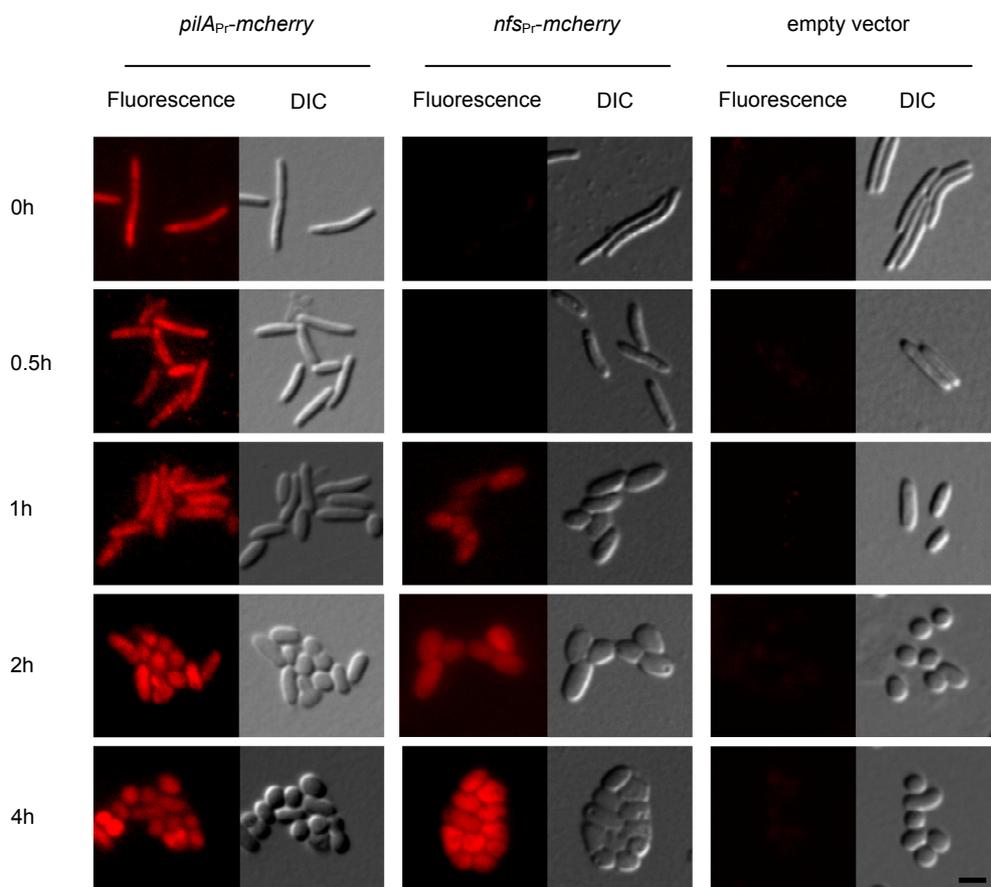

Figure 2-10 Expression analysis of PH1221 (*pilA_P-mcherry*, left), PH1220 (*nfs_P-mcherry*, center), and PH1222 (empty vector control, right) strains grown in CTT and induced with glycerol. Samples were taken at indicated time points, spotted on Agar slides and imaged with a fluorescence microscope. Bar: 1 μ m.

The experiment covers the time in which glycerol-induced vegetative cells convert into spheres as seen in the DIC images. *mcherry* under control of the *pilA*-promoter is constitutively expressed as seen for strain PH1221. Both rod shaped cells, shortening rods and spherical spores fluoresce. For strain PH1222 (empty vector control) only weak autofluorescence signals are detectable at any time point. However, in PH1220 where *mcherry* is fused to the *nfs*-promoter, fluorescence signals become detectable

after approximately one hour when cells are shortening. The signal is detectable from all cells that round up and increases until four hours. This suggests that *nfs* expression is below detection limits in vegetative cells but that proteins of *nfs* promoter controlled genes accumulate one hour after addition of glycerol.

2.3.2 Activation during starvation-induced sporulation

To determine *nfs* promoter activation during starvation-induced development, quantitative fluorescence measurements of developing submerged cultures were performed on the above strains.

Strains containing no *mcherry* display an approximately 2.9-fold gain in signal intensity over time which correlates with increasing autofluorescence of developing cultures (data not shown). Signal intensity of Mcherry derived from the *pilA*-promoter starts approximately twofold higher than in the control strain. The signal intensity increases and peaks at 36 hours 2.7-fold higher than at 0 hours. *nfs* promoter driven *mcherry*-expression starts at same levels as the negative control but increases 6.6-fold at 36 hours (Figure 2-11 a) correlating with darkening of the fruiting bodies (Figure 2-11 b).

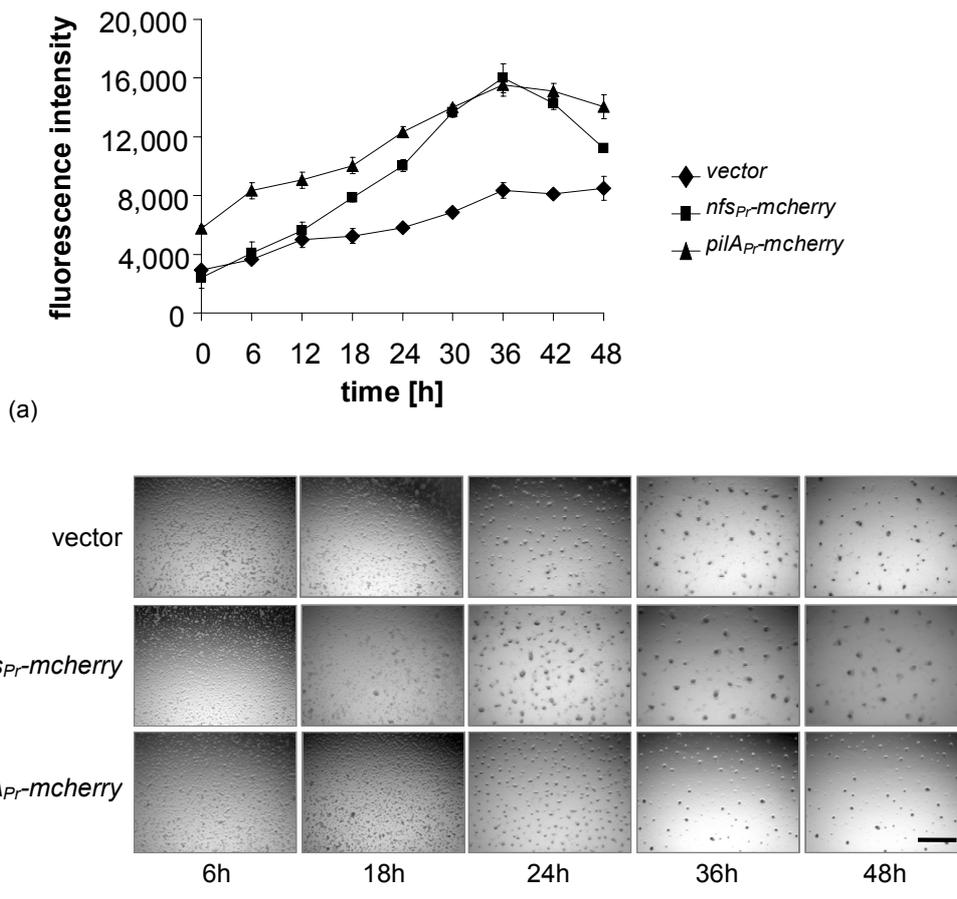

Figure 2-11 Quantitative fluorescence measurements of developing cultures. $2.5 \cdot 10^8$ cells were developed in black 24-well glass bottom dishes in submerged culture. (a) Mcherry specific fluorescence was determined every six hours. Experiments were carried out in triplicate. (b) Stereo microscope images of the developing cultures. The strains were imaged to confirm proper development (selected time points are shown). Bar: 1 mm.

These results suggest that *nfs* promoter driven proteins start to accumulate after 18 hours of development and reach highest levels at 36 hours reflecting continued expression. Otherwise, the curve of the signal intensity would adopt the slope of the control strain or decrease.

To distinguish which subpopulations of developing cells express *nfs* promoted *mcherry*, cultures that have developed for 36 hours were harvested and fruiting bodies were separated from peripheral rods by centrifugation (O'Connor & Zusman, 1991). The separated populations were then imaged with a fluorescence microscope.

While both rods and spores of the empty vector control strain displayed only weak autofluorescence signals, rods and spores from PH1221 (*pilA_{P_r}-mcherry*) produced strong fluorescence signals. In PH1220 (*nfs_{P_r}-mcherry*), only the background signal is detected from rods whereas spores emitted strong fluorescence suggesting that *nfs* is only expressed in the spore forming subpopulation of developing cells. This observation was confirmed by confocal laser microscopy of fruiting bodies. Fluorescing rods were only visible in strain PH1221 (*pilA_{P_r}-mcherry*) but not in PH1220 (*nfs_{P_r}-mcherry*) and the empty vector control (Figure 2-12 a).

We next sought to determine the patterns of Nfs protein accumulation during a starvation-induced time course. Only NfsA and B could be detected by immunoblot analysis (Figure 2-12 b). The proteins could be observed after 24 hours of development and they are still detected after one week. NfsC - H were not detectable by immunoblot. Therefore, it cannot be ruled out that these proteins display different expression and stability patterns during starvation-induced development.

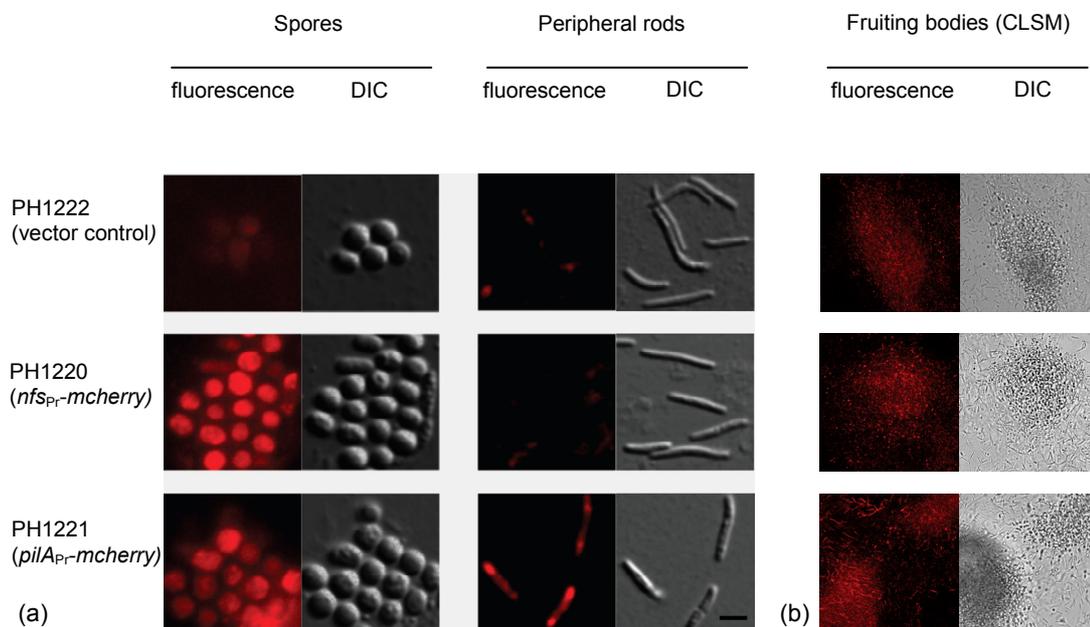

Figure 2-12 Fluorescence micrographs of cells from submerged culture. (a) Separated spores (left) and peripheral rods (right) after 36 hours development. Bar: 1 μ m. (b) Confocal laser scanning microscope images of fruiting bodies after 48 hours (microscopy was performed by Dr. Kai Thormann).

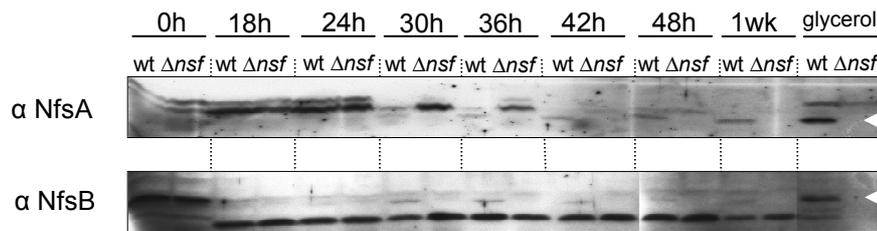

Figure 2-13 Anti-Nfs immunoblots on samples from developing cultures. Equal culture volumes were harvested at the indicated times of development, proteins were released by bead beating, resolved by poly-acrylamide gel electrophoresis, and probed with anti-sera specific to NfsA - H.

2.4 The Nfs proteins likely function together

2.4.1 Single *nfs* in-frame deletion mutants do not form glycerol-induced spores

To investigate whether all eight Nfs proteins are part of one functional unit, single *nfs* in-frame deletion mutants were generated with intact genes for the remaining *nfs* genes. The strains were characterized in terms of their ability to form glycerol spores. None of the mutants was able to form phase contrast bright spores but displayed a phenotype similar to the Δnfs mutant (**Figure 2-14**).

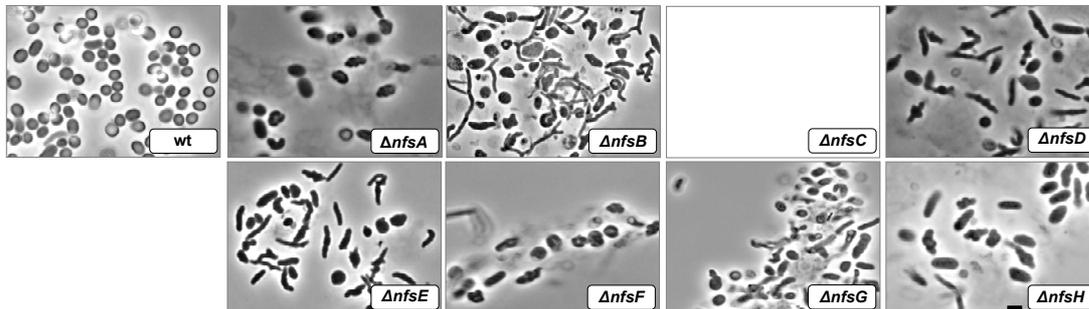

Figure 2-14 Phenotype of *nfs* single gene in-frame deletion mutants. Exponentially growing liquid cultures were induced with glycerol for twelve hours and imaged with phase contrast at 1000-fold magnification. Bar: 1 μ m.

The phenotypes of the seven single mutants are similar to the Δnfs mutant suggesting that each of the *nfs* genes is essential to form refractile spores and that the proteins may function together.

Several attempts to delete *nfsC* failed. We were not able to delete the entire gene or an internal fragment of 790 bp length. Recombining into up- or downstream regions as necessary precondition for a deletion was also not successful. Deletion by a recombineering approach using the existing *M. xanthus* cosmid library (Nils Hamann *et al.*, unpublished) was not possible because the *nfs* locus is not part of this library.

2.4.2 The Nfs proteins localize to the cell envelope

To assay the predicted subcellular localization of the Nfs proteins, cell fractionation experiments were performed and the separated fractions of soluble and insoluble proteins probed with Nfs antisera.

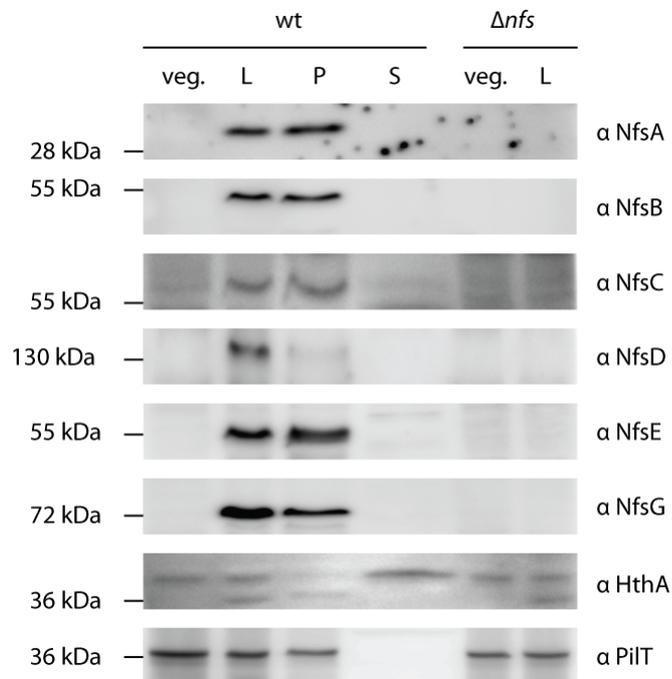

Figure 2-15 Subcellular localization of the Nfs proteins. Wild type (wt) and Δnsf liquid cultures were induced with glycerol for two hours. Cells were harvested, lysed by bead beating and ultracentrifuged to separate soluble proteins from insoluble proteins with membranes. The proteins were further separated by SDS-PAGE and probed with Nfs-antibodies. veg: uninduced control, L: whole cell lysate, P: insoluble pellet fraction, S: soluble supernatant fraction.

The DNA-binding protein HthA (Nielsen *et al.*, 2004) served as example for soluble proteins and PilT as control for membrane associated proteins. Interestingly, the Nfs proteins can be detected in the fraction of insoluble proteins which suggests that the proteins are membrane associated and agrees with the predicted cell envelope localization.

2.4.3 Stability of the Nfs proteins is reduced in single in-frame deletion backgrounds

The predicted interaction domains in NfsD, E and G suggest that the proteins may be part of a larger complex and act together. In that case, loss of one of the proteins may destabilize the putative complex. Proteins that are not longer part of the complex may then be less stable, i.e. they are subjected to proteolysis. To test this hypothesis, the mutants with single *nfs* in-frame deletions were induced with glycerol, lysed and the cell lysates probed with Nfs antibodies (Figure 2-16).

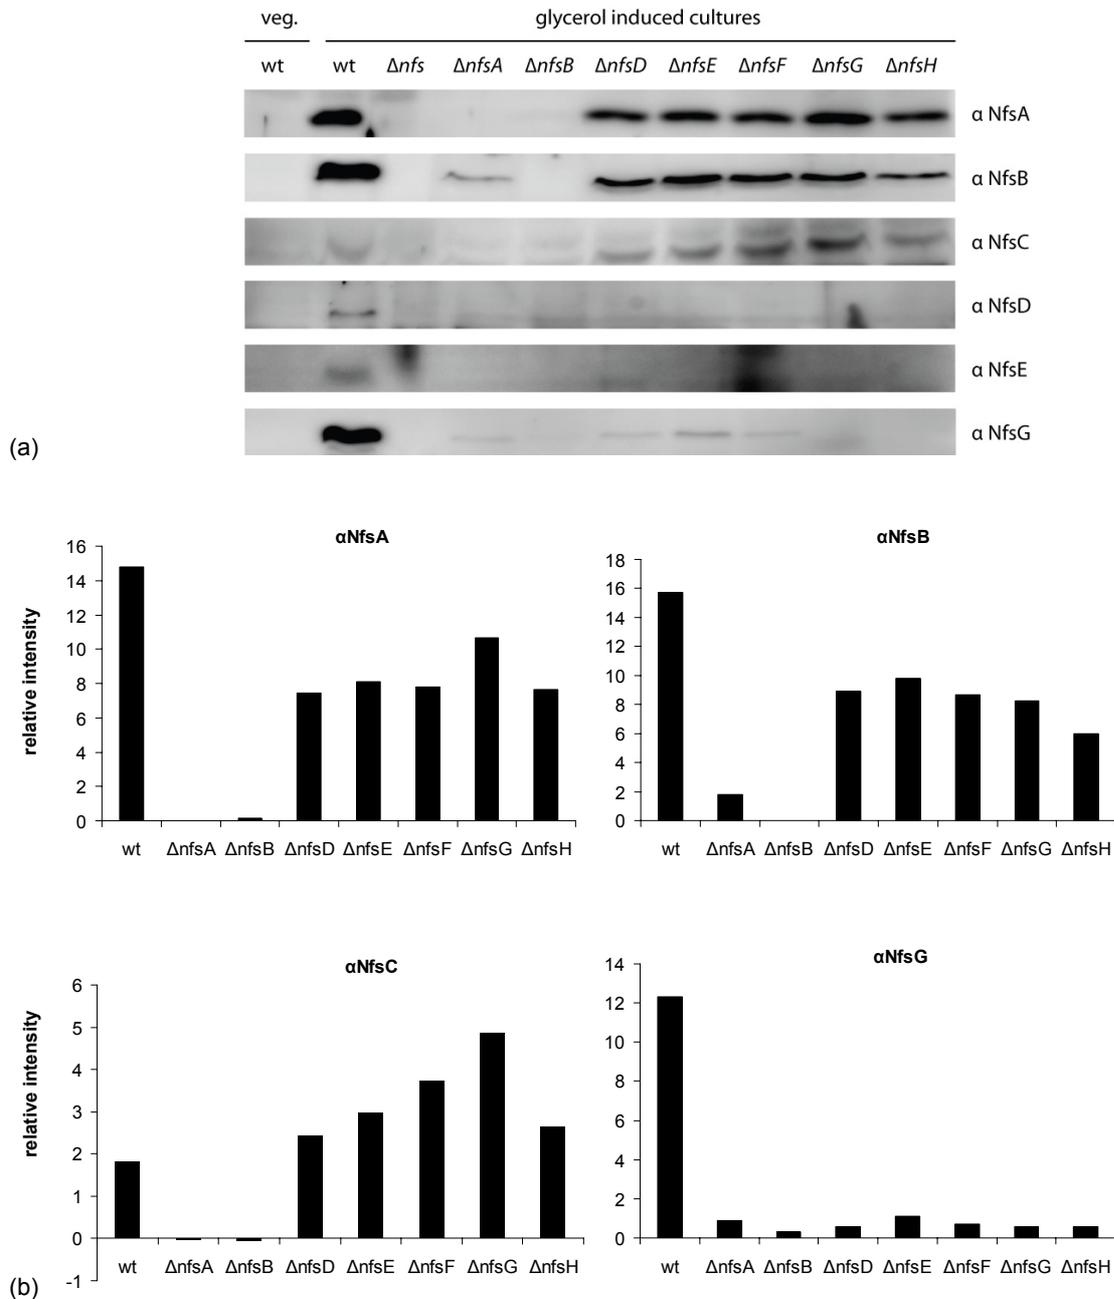

Figure 2-16 Western blot analysis on single in-frame deletion mutants. (a) Nfs immunoblots. Protein from cells that were induced with glycerol for two hours was released by bead beating. Equal protein concentrations were loaded on SDS-PA gels. Samples of uninduced (veg.) and induced wild type and induced Δnfs served as control. (b) Bar graphs represent signal intensities as determined by densitometric analyses.

The immunoblot results suggest that NfsA, B and C are affected by loss of any of NfsD, E and G proteins since NfsA, B and C are still detectable but with reduced signal intensities compared to wild type. However, the signal of NfsB is strongly reduced in the $nfsA$ background. Likewise, NfsA cannot be detected in the $nfsB$ background. NfsC is also not detectable in $nfsA$ and $nfsB$ backgrounds suggesting that stability of these three proteins depends on each other.

However, NfsD and E cannot be detected in any of the single mutants; and the signal of NfsG is strongly reduced. These results indicate that Nfs D, E and G are unstable if any of the remaining Nfs proteins is absent.

2.4.4 The *nfs* locus consists of two transcriptional units

As outlined in **Section 2.1.8**, the *nfs* locus consists of eight genes oriented in the same direction. However, between NfsC and D as well as NfsE and F and NfsG and H exist non-coding sequences that could contain additional promoter elements. To test if the whole 12.5 kB locus forms one single transcriptional unit, PCR on cDNA generated from glycerol-induced cells was performed. Negative controls included samples without added reverse transcriptase to verify absence of contaminating genomic DNA and samples without added template. The results suggest that the locus is transcribed in two separate units consisting of *nfsA* to *C* and *nfsD* to *H*.

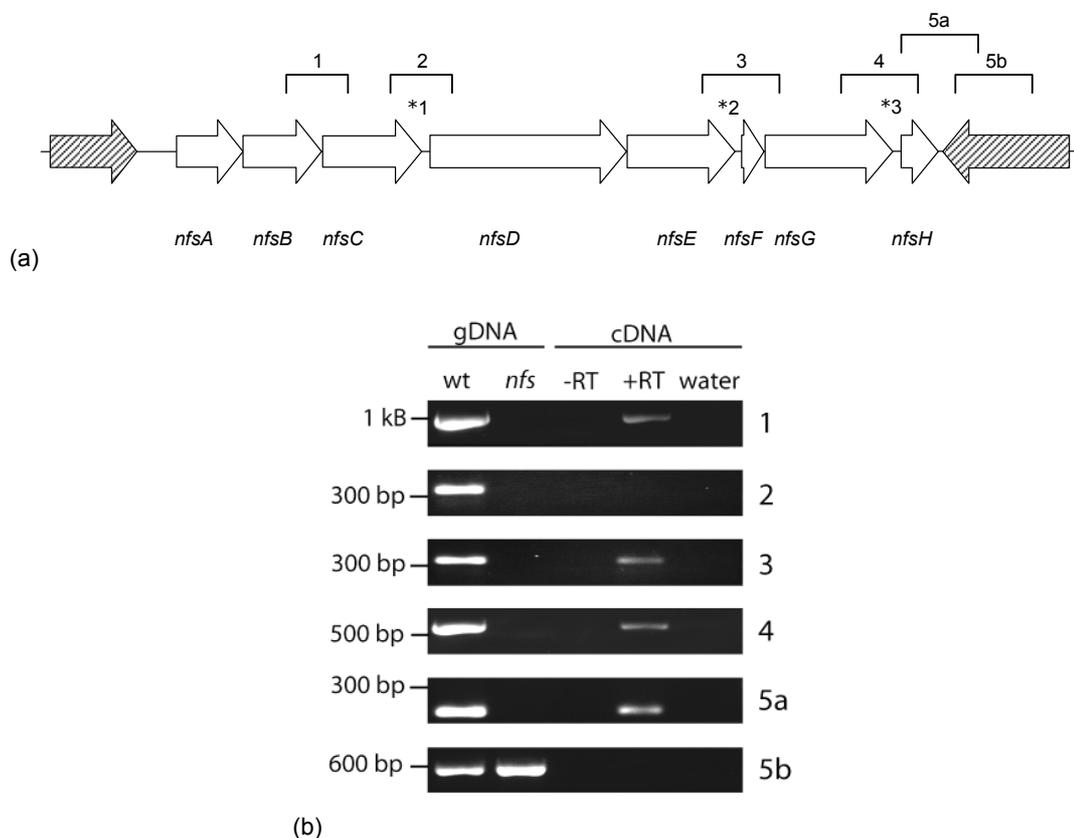

Figure 2-17 The *nfs* locus forms two transcriptional units. (a) Genetic organization of the *nfs* locus. Numbered brackets indicate the regions that were tested for presence of a continuous transcript. (b) PCR results. cDNA from glycerol-induced wild type cells was analyzed by PCR using oligonucleotide primers flanking the regions to be tested. Genomic DNA of wild type and Δnfs served as control. wt: wild type, *nfs*: *nfs* deletion strain, -RT: control reaction without added reverse transcriptase, +RT: reaction with reverse transcriptase, water: template-free control.

Notably, a transcript could be amplified with an oligonucleotide that bound 183 bases downstream of the *nfsH* stop codon (**Figure 2-17 a**, Bracket 5a). However, no PCR product was obtained with an oligonucleotide that bound 506 bases downstream (**Figure**

2-17 a, Bracket 5b) suggesting that the terminator region of the second transcript is located in between these two binding sites.

Interestingly, the two transcriptional units detected by PCR coincide with the two patterns of protein stability (Section 2.4.3) and protein accumulation (Section 2.3.1).

2.5 Expression of the Nfs proteins is changed in the *fruA* developmental mutant background

It has been shown that the developmental process in *M. xanthus* is controlled by a gene expression cascade and that later key or marker genes are not expressed if the development is blocked earlier by inactivation of a key regulator (Kroos, 2007) (Figure 1-6). Therefore, genes involved in development can be classified by their dependency on certain developmental key regulators.

To test if *nfs* expression depends on key developmental proteins, the *nfs* promoter-*mcherry* fusion was introduced into specific developmental mutant backgrounds. These strains were developed and fluorescence intensities were measured at distinct time points.

Figure 2-18 a suggests that fluorescence intensities of all four strains are about equal levels at the beginning of the time course. The signal of the vector control is slightly increasing due to growing autofluorescence during development. However, fluorescence signals of PH1220 (*nfs*_{Pr}-*mcherry*) and Ω 7536 (*exo*) with *nfs*_{Pr}-*mcherry* increase strongly by 6.6- and 5.4-fold until 36 hours. Fluorescence intensity of the *dev* mutant also increases but does not reach the level of the PH1220 and Ω 7536 (*exo*). However, fluorescence signals of *csgA* stay low and close to control levels (Figure 2-18 b). Interestingly, in the *fruA* mutant, fluorescence intensity increases 6.2-fold already at 24 hours (Figure 2-18 b). This transcriptional activation of *nfs* in the *fruA* mutant background was confirmed by an NfsB-immunoblot on samples from a developing culture of an independent *fruA* mutant (data not shown).

These results suggest that *nfs* expression is independent of *exo* and *dev* but dependent on the C-signal. Interestingly, the genes are expressed in the *fruA*-mutant. FruA is a central regulator of developmental gene expression. The *fruA* mutant is blocked in developmental progression during early mound formation. Beta-galactosidase assays have shown that several genes are deregulated in a *fruA* mutant (Ogawa *et al.*, 1996). The data suggest that FruA may be involved in *nfs* repression during early stages of development.

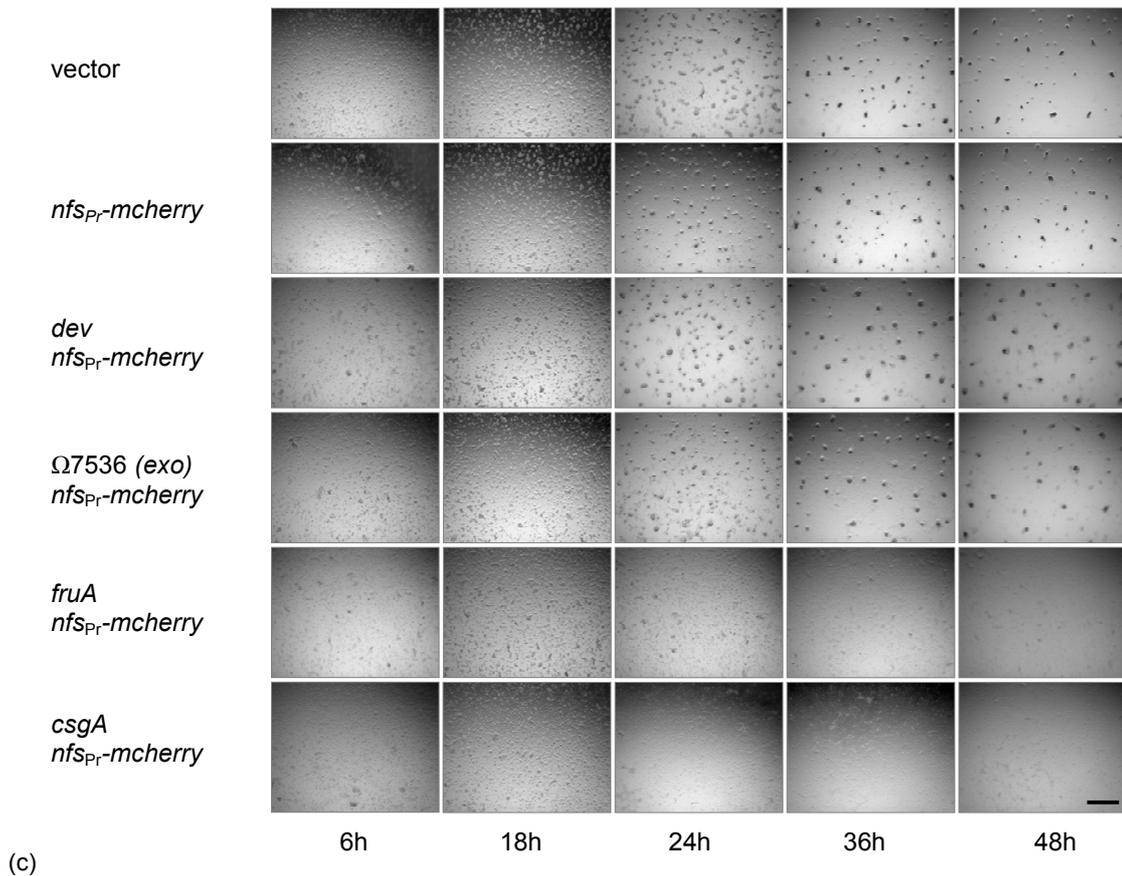

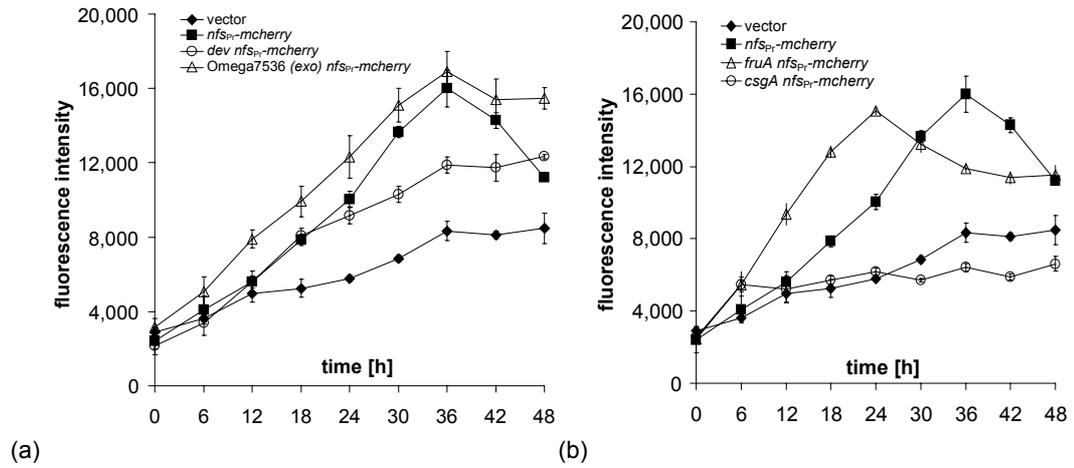

Figure 2-18 Quantitative fluorescence measurements of developmental mutants in submerged culture. Equal cell numbers were developed in 24-well black glass bottom dishes. *mcherry* specific fluorescence was determined at indicated time points. Experiments were carried out in triplicate. (a) Fluorescence intensities of the aggregating but not spore forming *dev* and Ω 7536 (*exo*) mutants are plotted together with the empty vector control and PH1220 where *mcherry* is under control of the *nfs* promoter. (b) Fluorescence intensities of the non-aggregating *fruA* and *csgA* mutants with the same controls as in (a). (c) Stereo microscope images of the cultures. Selected time points are shown. Bar: 1 mm.

2.6 Differences in protein glycosylation patterns of wild type and Δnfs were not detectable

Sequence analyses suggested that NfsC and E may be involved in protein glycosylation and NfsH may be a target for glycosylation. Glycosyltransferases are a large protein family involved in numerous processes mainly known from eukaryotic systems. Many of the characterized proteins play a role in cell wall associated polysaccharide metabolism (Iwai *et al.*, 2002a, Coutinho *et al.*, 2003). In bacteria, an increasing number of glycosylated proteins are known. In *B. subtilis*, spore coat proteins are glycosylated and in Gram-negative bacteria, exported or surface anchored proteins such as pili, adhesins and surface-layer proteins have been reported to be glycosylated (Power & Jennings, 2003, Messner, 2004, Schaffer & Messner, 2004). In *E. coli*, glycosylation of the exported cell adhesion mediating protein Ag43 by the action of the Aah and TibC glycosyltransferases has been observed. This protein modification takes place in the periplasm (Sherlock *et al.*, 2006). Since upon sporulation in *M. xanthus* spore-specific proteins are synthesized, and since spores of the *nfs* mutant appear less resistant and refractile, protein glycosylation patterns of wild type and the *nfs* mutant were analyzed. $\Omega 7536$ (*exo*) was also assayed because of its similar phenotype and putative function in carbohydrate metabolism and trafficking. For this purpose, cells were grown in liquid culture and induced with glycerol for four hours. Proteins were released by bead beating and separated by SDS-PAGE. The separated proteins were assayed for glycosylation. The protein glycosylation assay revealed no clear differences in protein glycosylation patterns between wild type and Δnfs . Likewise, between wild type and $\Omega 7536$ (*exo*) no clear differences were visible.

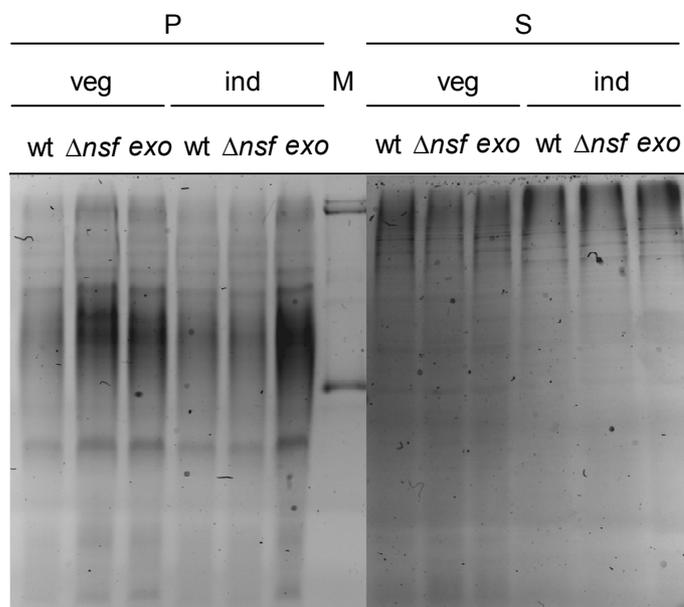

Figure 2-19 SDS-PA-gel stained for glycosylated proteins. Wild type, Δnfs and $\Omega 7536$ (*exo*) were induced with glycerol for four hours. Cells were harvested and disintegrated by bead beating. The cell lysates were divided into soluble and insoluble fractions by ultracentrifugation and proteins were separated by SDS-PAGE. The fixed gel was stained for glycosylated proteins and imaged at excitation of 300 nm wavelength. P: cell envelope fractions, S: soluble fractions, veg: uninduced cells, ind: glycerol-induced cells, M: glycosylation marker.

2.7 Cell wall synthesis

The *nfs* mutant displays an aberrant spiral like cell morphology during elongation. Spiral-like structures in rod-shaped cells have been identified before. For example, the filament forming protein MreB was identified to assemble in spiral-like structures and as one key organizer of bacterial cell shape and cell wall synthesis. To test the hypothesis that the Nfs proteins are involved in co-ordinated cell shape remodelling and cell wall synthesis during outgrowth, peptidoglycan synthesis was studied by fluorescence labelling with vancomycin.

Vancomycin inhibits cell wall synthesis by forming stable complexes with the C-terminal d-Ala-d-Ala residues present in the lipid II-linked disaccharide pentapeptide cell wall precursors and in the nascent, un-cross-linked peptidoglycan. This blocks access of cell wall synthesizing penicillin binding proteins (PBPs) to their substrates, resulting in the inhibition of cell wall biosynthesis (Reynolds, 1989). Fluorescently labeled Vancomycin (VanFL) can therefore be used to identify places in the bacterial cell wall where new peptidoglycan is synthesized (Pereira *et al.*, 2007).

Exponentially grown wild type and mutant cells were stained as described in Materials and Methods (**Section 4.10**). As control and to test if the staining is specific to nascent peptidoglycan, cells were also grown to stationary phase. Since cells in stationary phase do almost not grow anymore, their rate of peptidoglycan synthesis was expected to be much lower compared to exponentially growing cells.

The signal of logarithmic growing cells appeared as patches dispersed over the entire cell. Cells of stationary phase displayed strong fluorescence signals towards the cell poles and sometimes at mid-cell (**Figure 2-20**). Since it is unlikely that stationary phase cells have strong turnover of peptidoglycan at the cell poles, the intense signal may be due to autofluorescence of storage compounds and unspecific binding of the stain. The background signals towards the cell poles can also be observed in unstained control cells but to lesser extend. Application of the staining technique to germinating wild type spores or re-elongating induced Δnfs cells led to occurrence of patchy fluorescence signals sometimes with intense spots at the tips of outgrowing spheres (**Figure 2-20**) but these cells were fragile and prone to lysis after fixation.

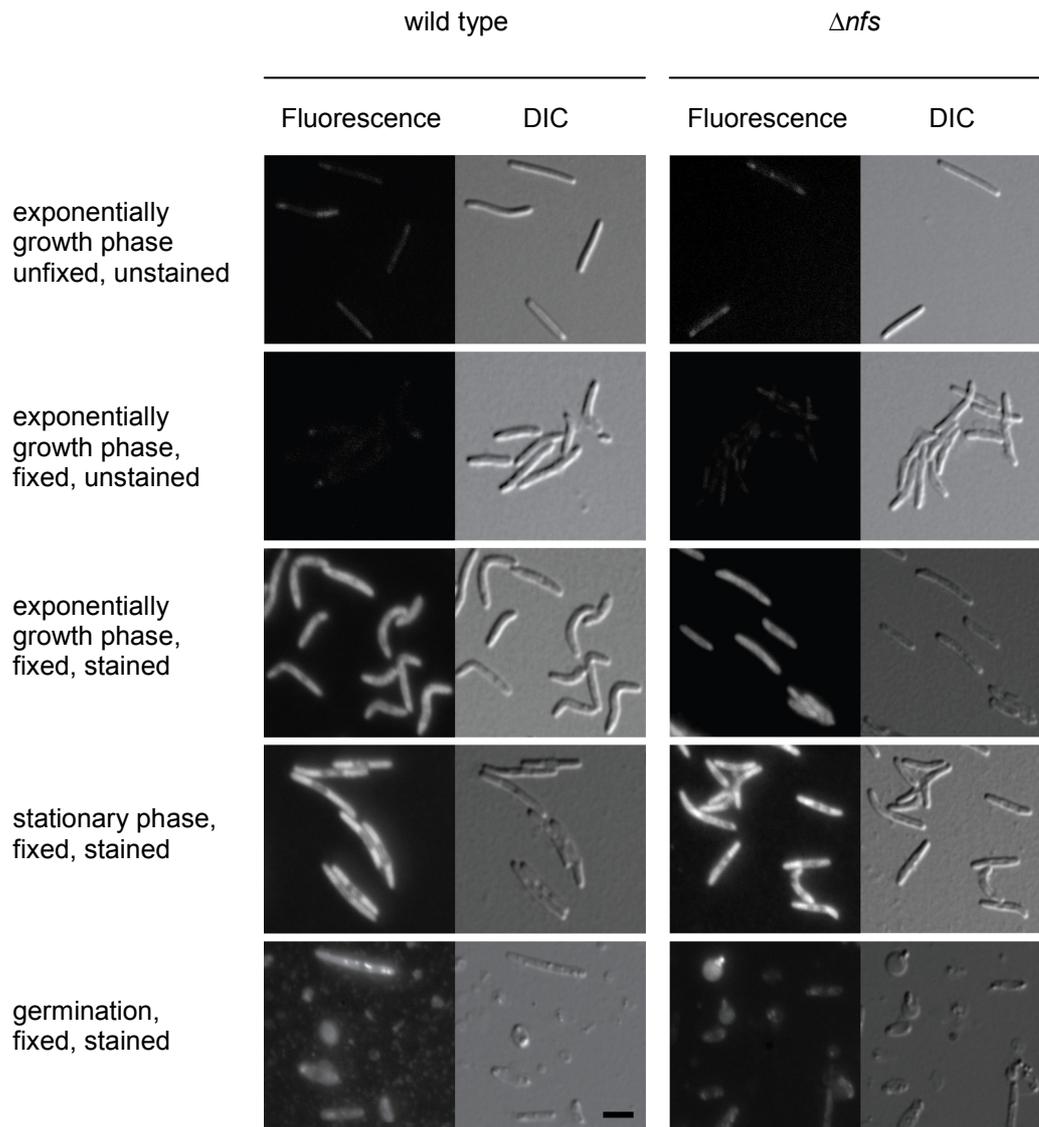

Figure 2-20 Fluorescence images of VanFL stained cells. Wild type and Δnfs was grown in liquid culture and 1 ml samples were taken from logarithmic and stationary phase. Additionally, samples of germinating glycerol spores were used. Cells were fixed, stained and imaged under the fluorescence microscope. Bar: 1 μ m.

2.8 Role of MreB during spore formation and germination

In most non-cocoid bacteria, certain proteins are present and responsible for maintenance of a distinct cell shape. In most cases, these proteins are highly conserved and essential or, if there are several homologues in one genome, at least important for a normal cell shape.

One of these proteins is the actin-like MreB. This protein is able to polymerize into twisted filaments that are attached to the cell membrane and traverse the longitudinal axis of the cell (Varley & Stewart, 1992, Figge *et al.*, 2004). Depletion of MreB in *Caulobacter crescentus* turns the rod-like cells into spheres and repletion of the protein reconstitutes normal rod cell shape (Figge *et al.*, 2004).

It is thought that the spiral-like MreB filaments localize the peptidoglycan synthesizing enzyme complexes during lateral growth and cell division (Figge *et al.*, 2004) (Carballido-Lopez, 2006) (den Blaauwen *et al.*, 2008). Therefore, assembly of new cell wall material occurs at distinct positions and coordinated by the cytoskeleton. To date, some proteins have been shown to co-localize with the MreB filaments (Divakaruni *et al.*, 2005, den Blaauwen *et al.*, 2008) and likely interact directly or indirectly (Kruse *et al.*, 2006, Bendezu *et al.*, 2008).

The observed phenotype of the *nfs* deletion mutants during glycerol induction suggests that there could be an uncoupling between the cytoskeleton protein MreB scaffolds and rapid cell wall conversion. Hence, the *nfs* genes may encode proteins that directly or indirectly interact with MreB and coordinate cell wall remodelling during sporulation and germination. To characterize the behaviour of MreB during the transition from rods to spherical spores and, during germination, back again to rods with respect to MreB synthesis and degradation as well as localization and its polymeric state could serve as a tool to understand how coordinated cell shape changes in *M. xanthus* are accomplished.

2.8.1 *In-vivo* labelling of MreB

To analyze the role of *M. xanthus*' MreB in cell morphogenesis and to visualize the behaviour of MreB during spore formation and cell elongation *in vivo*, the protein was fused both N- and C-terminal to the green fluorescent protein (Gfp) and the enhanced Gfp (March *et al.*, 2003, Chudakov *et al.*, 2005). To avoid the natural green autofluorescence background signal, the protein was also fused to Venus, a yellow fluorescing Gfp derivative.

In *M. xanthus*, MreB is likely essential under standard growth conditions. Several attempts to recombine in the *mreB* gene were not successful. Notably, high magnesium concentrations in the medium did not support growth of *M. xanthus mreB*-mutants (data not shown) as contrasted by *B. subtilis* (Formstone & Errington, 2005). To introduce a C-terminal label by homologous recombination likewise failed suggesting that the C-terminal labelled MreB is not functional (Table 2-14).

Mutants only were obtained for N-terminal fusions that were introduced at the Mx8 phage attachment site leaving the native *mreB* intact. However, distinct fluorescence signals above background were not detectable in these strains (**Figure 2-21**). A possible reason for this result is that the labelled MreB is not as efficiently assembled into the filaments as the simultaneously present native protein.

Table 2-14 Results of in vivo fluorescent labelling of MreB

Construct	Integration	Results
<i>mreB</i> (C-term)- <i>venus</i>	homologous	no colonies
<i>mreB</i> _{P_r} - <i>gfp</i> - <i>mreB</i>	Mx8-att	no specific fluorescence
<i>mreB</i> _{P_r} - <i>egfp</i> - <i>mreB</i>	Mx8-att	no specific fluorescence
<i>mreB</i> _{P_r} - <i>venus</i> - <i>mreB</i>	Mx8-att	no specific fluorescence
<i>mreB</i> _{P_r} - <i>gfp</i>	Mx8-att	no specific fluorescence
<i>mreB</i> _{P_r} - <i>egfp</i>	Mx8-att	no specific fluorescence
<i>pilA</i> _{P_r} - <i>gfp</i> - <i>mreB</i>	Mx8-att	multiple phenotypes

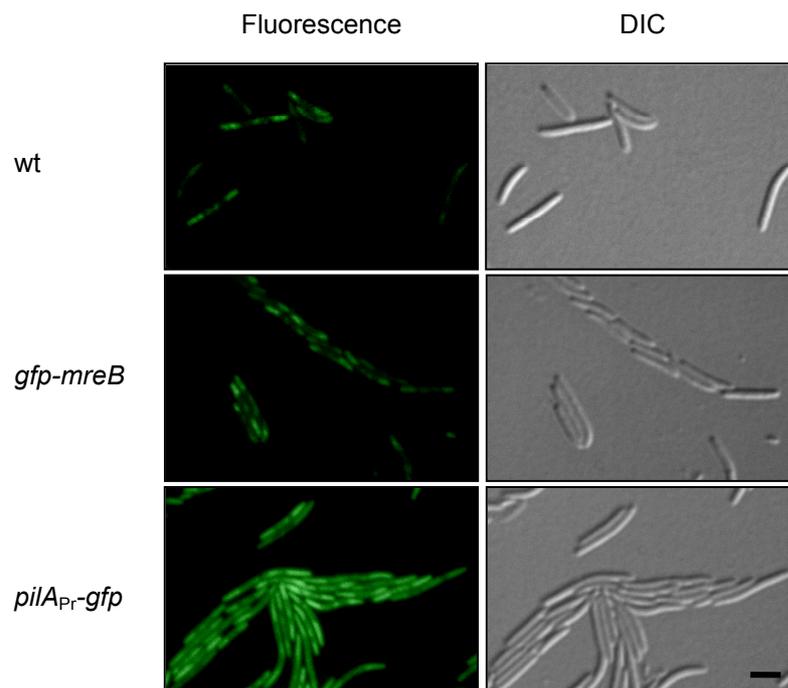

Figure 2-21 Fluorescence images of wild type, PH1250 (*gfp-mreB*) and PH1251 where *gfp* is under control of the *pilA*-promoter. Vegetatively growing cells were spotted on agarose pads and imaged with a fluorescence microscope. Bar: 1 μ m.

2.8.2 Overexpression of MreB leads to cell shape defects

To increase the amount of labelled MreB per cell, a mutant was generated containing *gfp-mreB* under control of the strong *pilA*-promoter leading to overexpression of the fusion protein. Overexpression was confirmed by immunoblot (Figure 2-25). The obtained mutants grew slowly, colonies were tan and cells were non-motile. However, after incubation for several days, motile revertant cells spread from colony edges. The microscopic image revealed that many cells displayed severe cell shape defects such as spherical cells of various sizes (Figure 2-22 a).

The fluorescence images suggest that some cells contain bright fluorescing filaments associated with cell shape defects (Figure 2-22 b). These fluorescing filaments are also known from other studies (Karczmarek *et al.*, 2007). Furthermore, some single cells displayed an alternate punctuate fluorescence pattern along the cell axis as expected for the spiral forming MreB (Figure 2-22 c). Both the fluorescing filaments and the occasionally observed punctuate fluorescence pattern of *mreB* overexpressing cells suggest that *in vivo* labelling of MreB in *M. xanthus* is in principle possible, but expression of the labeled *mreB* needs a tight control as, for example, by an inducible promoter.

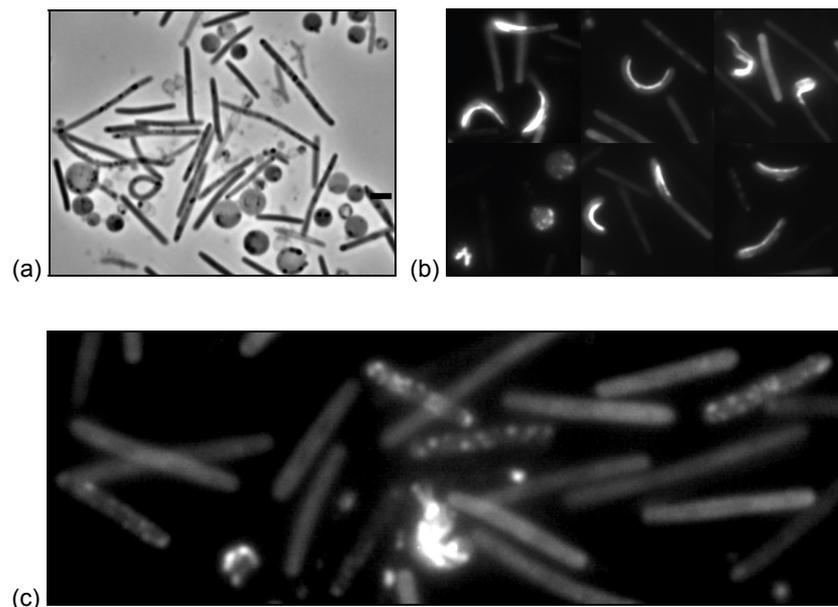

Figure 2-22 Phase contrast and fluorescence images of PH1252 (*pilA_P-mreB*). (a) Cells were grown in liquid, spotted on an agarose pad and imaged at 1000-fold magnification. (b) Malformed cells with bright fluorescent filaments are visible (combined image). (c) Single cells with punctuate fluorescence patterns.

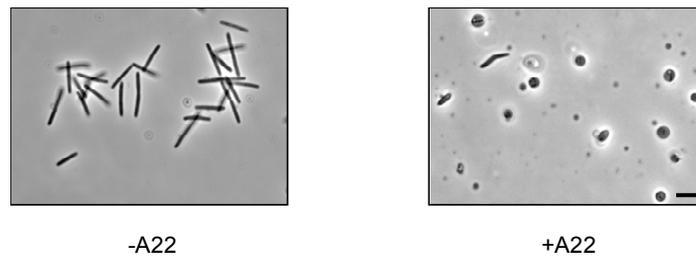

Figure 2-23 Phase contrast images of wt cells treated with 20 µg/ml A22 (dissolved in methanol) for 12 hours. The left image shows a control where the equal volume of methanol was added. Bar: 1 µm.

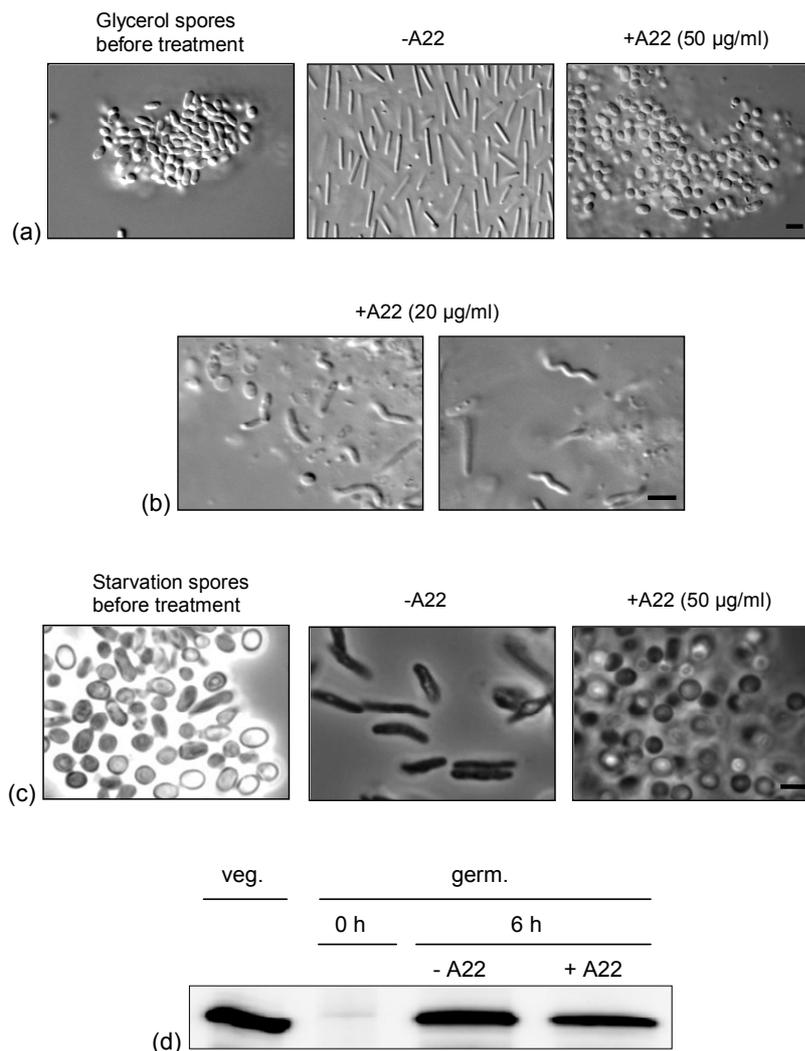

Figure 2-24 Micrographs of wild type spores in CTT treated with A22. (a) Glycerol spores were harvested, washed and resuspended in CTT medium. The suspension was split and A22 was added to a final concentration of 50 µg/ml. Cultures were incubated for twelve hours shaking at 32°C. Cells were imaged at 600-fold magnification with DIC. (b) Glycerol spores were treated as in (a) but A22 was applied to a final concentration of 20 µg/ml. (c) Starvation-induced spores were harvested after five days development in submerged culture. Samples were sonicated to disrupt fruiting bodies and peripheral rods and centrifuged to pellet the spores. Spores were resuspended in CTT medium and the suspension split into two samples and treated as in (a). Cells were imaged after six hours with phase contrast at 1000-fold magnification. Bar: 1 µm. (d) MreB immunoblots on samples from (c). Spores were germinated in CTT for 6 hours. veg.: vegetative cells (control), germ.: spores germinating in CTT with and without A22 (50 µg/µl) added.

2.8.3 *M. xanthus* cells are susceptible to A22 treatment

A second approach to manipulate MreB and cell shape is to add *S*-(3,4-dichlorobenzyl)isothiourea (A22) to growing cells (Iwai *et al.*, 2002b). Upon addition of A22, MreB filaments disappear and cells round up and lyse as shown for *E. coli*, *B. subtilis* and *C. crescentus* (Figge *et al.*, 2004, Carballido-Lopez & Formstone, 2007, den Blaauwen *et al.*, 2008) To test if A22 also affects *M. xanthus*, vegetative cells were incubated with the compound.

The results show that *M. xanthus* cells round up upon addition of A22. This suggests that *M. xanthus* MreB is susceptible to A22 and essential to maintain a rod shaped cell morphology (Figure 2-23).

2.8.4 A22 inhibits spore germination

To test the hypothesis that MreB polymerization is not only essential to maintain rod-like cell morphology but that is also crucial to generate rod-shaped cells from spheres in *M. xanthus*, A22 was added to both glycerol and starvation spores in rich medium.

The results of this experiment suggest that A22 inhibits spore germination at a concentration of 50 µg/ml and above (Figure 2-24 a and c), data for higher concentrations not shown). Interestingly, at a concentration of 20 µg/ml, glycerol spores start to germinate after 12 hours and most of the cells lyse. During this state, few spiral-formed cells are visible (Figure 2-24 b). However, since A22 is not stable in aqueous solutions, the concentration may have dropped below 20 µg/ml at this time.

The phase contrast images of developmental spores suggest that spores do not germinate in presence of 50 µg/ml A22 but their refractivity decreases. This probably means that spores turn into spherical cells when A22 is present in rich medium (Figure 2-24 c).

2.8.5 Overexpression and purification of MreB for antibody generation

To generate specific tools to study MreB in more detail, the *M. xanthus mreB*-gene was cloned into pET32a⁺ (Invitrogen) resulting in plasmid pFM50 containing several tags for protein affinity purification. This plasmid was transferred into different *E. coli* strains optimized for heterologous protein expression. The purified protein was to serve as antigen to generate anti-MreB antibodies in rabbits (Eurogentec).

Several attempts to obtain the protein soluble were not successful. Therefore, the protein was harvested and purified from inclusion bodies. Obtained antisera were tested for specificity against *M. xanthus* cell lysates and the inclusion body fraction from induced *E. coli* cells. These tests revealed that the antisera needed to be affinity purified (data not shown). After purification, the antisera were of sufficient sensitivity and specificity as shown by immunoblot (Figure 2-25).

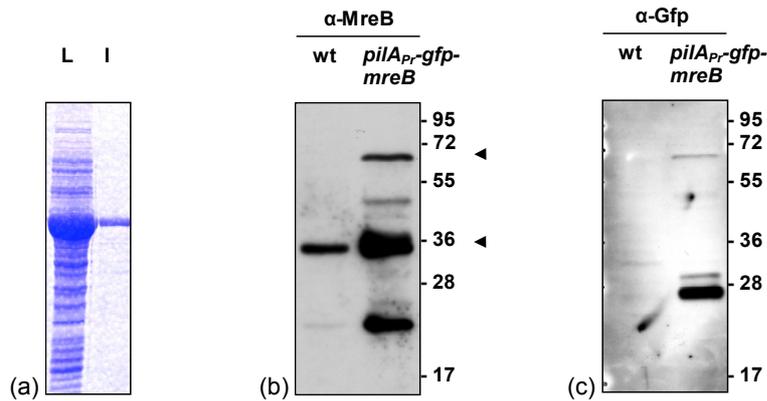

Figure 2-25 Purification of anti MreB antisera. (a) Cell lysate of *mreB* overexpressing *E. coli* BLADE3 pLysS loaded on a SDS-PAGE gel. The MreB containing inclusion bodies were separated by centrifugation at 600 x g. L: whole cell lysate, I: separated inclusion bodies. (b) Test of purified antiserum against *M. xanthus* cell lysates. Samples of a *gfp-mreB* overexpressing strain were probed as control. wt: *M. xanthus* wild type, *pilA_{Pr}-gfp-mreB*: *gfp-mreB* overexpressing strain PH1252. (c): Same samples as in (b) but probed with anti Gfp antibodies. Calculated molecular weights: MreB: 36.5 kDa, Gfp: 26.9 kDa, Gfp-MreB: 65 kDa.

2.8.6 The fate of MreB depends on the sporulation pathway

To test if MreB becomes degraded or only depolymerized upon spore formation, a time course experiment of both glycerol- and starvation-induced spore formation was carried out. Cells and spores were lysed by bead beating and equal protein concentrations for each time point were separated by SDS-PAGE. The samples were blotted and probed with MreB antibodies. Both wild type and Δnfs were tested to determine if MreB is regulated differently in the deletion mutant.

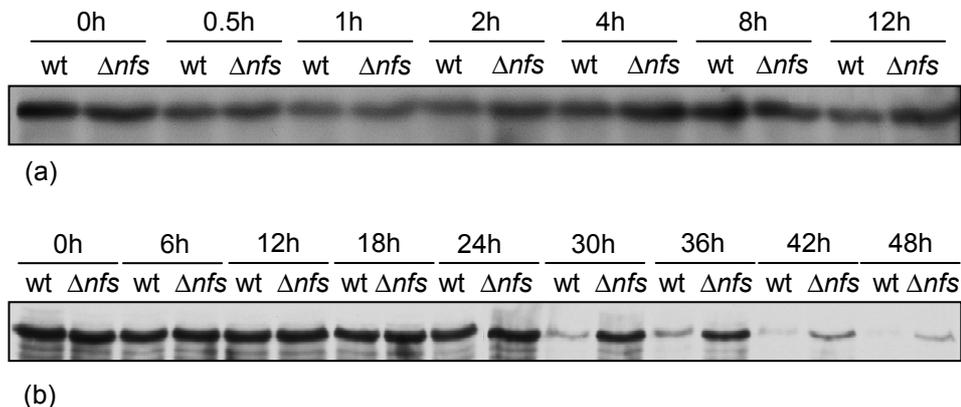

Figure 2-26 Anti MreB immunoblots on glycerol- and starvation-induced sporulating cells. (a) Glycerol induction time course. Wild type and Δnfs were induced with glycerol and samples were taken at indicated time points. Proteins were released by bead beating and separated by SDS-PAGE. (b) The same strains as in (a) were developed in submerged culture and lysed as the glycerol-induced cells. To distinguish relative MreB levels at distinct time points, all samples were adjusted to equal protein concentrations.

The immunoblots suggest that MreB can be detected during the whole glycerol spore induction time course in similar amounts. This means that the protein is not degraded although cells round up and form spores. However, during starvation-induced development, MreB specific signals start to decrease after 30 hours suggesting that the protein becomes degraded. Additionally, the timing of this degradation is slightly different in the Δnfs mutant. In this strain, the MreB signal decreases after 42 hours. Since developmental spores of the Δnfs mutant are less refractile and display reduced viability, this may reflect perturbed cell wall reorganization.

Interestingly, immunoblot results suggest that starvation-induced spores synthesize MreB *de novo* upon germination but do not elongate in the presence of A22 (**Figure 2-24 c and d**). This result suggests that MreB polymerization is essential for spore germination.

2.8.7 MreB subcellular localization

Sequence analysis of MreB suggests that the protein is cytoplasmic. However, it has been reported that MreB has a strong membrane affinity (Chiu *et al.*, 2008). The mechanism by which MreB is directly or indirectly attached to the membrane is not yet known. Under native conditions, most of MreB is present in its polymerized form as filaments, protofilaments or oligomers. These polymers are sedimented by ultracentrifugation together with the insoluble cell envelope fraction.

As shown above, the protein seems not to be degraded during glycerol-induced sporulation. Therefore, it is likely that the MreB filaments are disassembled and the protein is kept in its monomeric or in an oligomeric state. These mono- or oligomers then could detach from the membrane allowing cells to round up.

Immunoblot analysis on separated soluble and cell envelope fractions of glycerol-induced cells suggest that MreB is still associated with the membrane when cells form glycerol spores. This suggests that MreB stays in its polymeric and/or membrane attached state during glycerol spore formation and is not cytoplasmic dispersed.

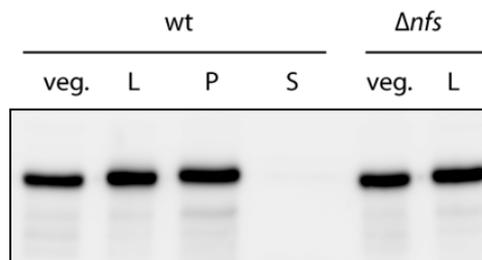

Figure 2-27 Subcellular localization of MreB after glycerol induction. Wild type (wt) and Δnfs liquid cultures were induced with glycerol for two hours; harvested, lysed by bead beating and ultracentrifuged to separate soluble proteins from insoluble proteins with membranes. Samples are the same as in **Figure 2-15**. Proteins were separated on a SDS-PAGE and probed with MreB antibodies. veg: uninduced control, L: whole cell lysate, P: insoluble pellet fraction, S: soluble supernatant fraction.

3 DISCUSSION

3.1 Micro array analysis

3.1.1 Up-regulation of sporulation markers indicates that glycerol- and starvation-induced spore formation share core processes

To better understand the process of spore formation in *M. xanthus*, we applied transcriptome profiling of glycerol induced spore formation by micro array analysis. This approach to use the glycerol-induced sporulation as model for *M. xanthus*' spore formation in general has been previously proposed (Dworkin & Gibson, 1964) and was applied in several early studies. However, the model system became disregarded mainly because of differences in thickness of the spore envelope seen in electron micrographs (O'Connor & Zusman, 1999). Additionally, proteins S, W and C, present in starvation induced spores, are absent in glycerol spores. Interestingly however, deletion of the gene encoding for protein S has no effect on spore formation (Komano *et al.*, 1984). Moreover, both spore types share many characteristics such as resistance to heat, sonication and detergents (Sudo & Dworkin, 1969), spherical shape and refractivity in phase contrast, and both spore types contain protein U. Additionally, both pathways induce a β -lactamase activity (O'Connor & Zusman, 1997).

Analysis of our micro array data suggests that most of the described sporulation marker genes are up-regulated such as *prU* (encoding for protein U) which is one of the most highly activated genes, *ops* (encoding for protein S1), *fdgA*, *exo*, *sigB* and *C*, *nla6*, *mSPA* and *C* (where *mSPC* represents also one of the most highly activated genes), *aceA* and *B* (encoding for glyoxylate cycle enzymes), *treS* (encoding for trehalose synthase). Conversely, genes that have been described to play a role in signaling, aggregation and non-spore forming subpopulations during starvation-induced development such as *asg* (encoding for A-signaling genes), *csg* (encoding for the C-signal), *popC*, *frzCD* and *devTSR* as well as the gene for myxobacterial hemagglutinin (MBHA) which is known from non-aggregating peripheral rods, are not regulated. This indicates that glycerol induction specifically activates the core sporulation process.

Interestingly, we also found *tps* (encoding for spore coat protein S) weakly up-regulated as contrasted by a previous beta galactosidase assay based report that suggests that *tps* is not transcribed during glycerol spore formation (Downard & Zusman, 1985). The reason for this difference may be the unequal sensitivity of both methods. Unexpectedly, we found three genes up-regulated which to date are only known to play a role in aggregation during starvation-induced development. These genes are *fruA*, *mrpC* and *actB*. Interestingly, all three genes are thought to act as transcriptional regulators during starvation-induced development, but intriguingly, *mrpC* and the *actB* mutant seem to have a glycerol-induced sporulation defect whereas the *fruA* mutant forms normal refractile glycerol spores (Müller & Higgs, unpublished data and (Ogawa *et al.*, 1996)). These results suggest that the regulated target genes of MrpC, ActB and

maybe FruA are not only involved in early stages of aggregation and formation of fruiting bodies but also directly in spore formation. Since the *mrpC*, *actB* and *fruA* mutants are defective in starvation-induced aggregation, the role of these genes in spore formation may be masked by the inability of the mutants to form fruiting bodies. Glycerol-induced spore formation would provide an appropriate tool to analyze putative targets of these regulators during spore formation.

The genes for the alternative sigma factors B (*sigB*) and C (*sigC*) are highly up-regulated. Target sequences for these sigma factors have not been published. However, deletion of *sigB* affects stability of mature spores. Therefore, *sigB* is proposed to be involved in maintaining the dormant stage of spores (Apelian & Inouye, 1990). Up-regulation of the late-stage sigma factor B supports this idea in particular, since peak expression of *sigB* is not at the beginning of the time course but after two hours. *sigC* is highly transcribed throughout the whole time course. Expression of *sigC* during glycerol-induced sporulation has been reported (Apelian & Inouye, 1993) but inactivation of *sigC* alone likely does not interfere with both glycerol- and starvation-induced spore formation. However, the mutant forms fruiting bodies on semi-rich media (Apelian & Inouye, 1993). Therefore, it is thought that SigC is involved in repression of fruiting body formation but not sporulation in the presence of nutrients, which also matches the conditions of glycerol-induced spore formation. This suggests that *sigC*, although consistently and highly activated, is not actually a core sporulation gene.

NtrC-like transcriptional activators are a second group of regulatory proteins that have been demonstrated to play a role in development. At least four of these genes (*nla4*, *6*, *18* and *24*) have been reported to cause both a glycerol- and a starvation-induced sporulation defect upon deletion (Caberoy *et al.*, 2003). However, target DNA binding consensus sequences of the regulatory proteins have not yet been published. We found *nla6* up-regulated while *nla4*, *18* and *24* were not regulated. NtrC-like activators mostly act as response regulators in signal transduction systems. Therefore, the genes do not necessarily need to be up-regulated to function. More likely, the proteins are constitutively synthesized and are activated by respective signaling systems. *nla6* seems to be an exception. It has been studied in more detail and a putative binding consensus sequence for the protein has been proposed (K. Giglio, 34th International Conference on the Biology of the Myxobacteria). One of the predicted binding sites lies upstream of *Mxan_3259*, the leading gene of a highly activated gene cluster encoding for putative membrane associated proteins involved in polysaccharide metabolism (Table A-15). Other putative targets of Nla6 are genes *Mxan_2688* through *Mxan_2690* which are also up-regulated in our data and might be involved in lipo- or exopolysaccharide synthesis. Notably, *Mxan_2689* may be involved in synthesis of alginate, an exopolysaccharide essential for cyst-formation in *Azotobacter* (Nunez *et al.*, 1999) (Moreno *et al.*, 1998). Therefore, these gene clusters represent excellent candidates for further study of spore envelope biogenesis. These data also may suggest that Nla6 acts as an activator of sporulation-specific genes involved in spore envelope synthesis. Real-time PCR analysis of sporulation marker genes, immunoblot analysis on spore-specific proteins in the *nla6* mutant and more detailed analysis of the target DNA-binding sequence could test this hypothesis.

The observation that most sporulation marker genes are up-regulated in the micro array data suggests that the oligomer-based micro arrays from the TIGR institute and the optimized hybridization protocol which we employed provide reliable data. In summary, analysis of the micro array results revealed that the glycerol-induced sporulation process is a suitable model for the core sporulation pathway in *M. xanthus*. Our transcriptional profiling may also be advantageous over proteomics approaches that largely depend on solubilization and mobility of the isolated proteins.

3.1.2 Regulated processes and regulation patterns

Genes of all functional categories are represented in the large number of significantly regulated genes. To analyze which functional groups of genes and which putative processes are mostly subjected to differential regulation, the genes were first grouped based on their assigned functional category and the genes in each category were divided into up- and down-regulated genes. We found that genes involved in 'protein synthesis' (such as ribosomal proteins) and genes encoding for proteins involved in respiration and electron transport (**Figure 2-3** and **Table A-15**) are down-regulated suggesting that that glycerol-induced cells reduce metabolism and synthesis of macromolecules. However, transcription of these genes does not appear to be completely shut down which suggests that they are still transcribed or their mRNA stays stable during glycerol-induced spore formation. These results are consistent with previous biochemical analyses showing that respiration rates of glycerol-induced cells decrease. Likewise, net synthesis of protein, DNA and RNA was found to decline (but not cease) within the first two hours after addition of glycerol (Bacon *et al.*, 1975).

The surprisingly high proportion of up-regulated genes reflects the fact that glycerol-induced sporulating cells do not simply convert into dormant vegetative cells, but instead form distinct entities which acquire very different structural and metabolical properties. This is emphasized by the high proportion of regulated genes in the categories 'energy metabolism' and 'central intermediate metabolism'. Similar numbers of genes in these categories are up- and downregulated suggesting that sporulating cells switch from actively growing to a non-growing but still active state as new spore specific proteins and envelope material need to be synthesized. For example, all seven of the genes encoding for enzymes involved in glycolysis or gluconeogenesis are found up-regulated. Another interesting result is the high up-regulation of the genes encoding for glyoxylate cycle enzymes (*Mxan_6441* and *Mxan_6442*, **Table A-15**). These results suggest activation of carbohydrate synthesis during spore formation. Previous reports have shown that 75% of the glycerol-induced spore coat consists of glucose and galactosamine (Kottel *et al.*, 1975). *M. xanthus* cannot not utilize carbohydrates as a carbon source (Bretscher & Kaiser, 1978) and the growth medium does not contain significant amounts of sugars. The glycerol added to induce sporulation does not serve as precursor for the carbohydrates in the spore coat because it has been reported that only minor amounts are incorporated (Sadler & Dworkin, 1966). Previous analyses of enzymatic activities have also shown that gluconeogenesis and glyoxylate cycle enzymes are much more active during glycerol-induced spore formation (Filer *et al.*, 1977). Together, these observations suggest that synthesis and export of large amounts

of carbohydrates necessary for spore formation may be due to up-regulation of the related genes.

Similarly, *treS*, encoding for trehalose synthase, was found to be up-regulated. Trehalose is a common bacterial carbohydrate storage compound, but is also synthesized during adaptation to osmotic shifts (Elbein *et al.*, 2003). Therefore, the up-regulation could be a side effect of adding glycerol which leads to changes of the osmotic conditions. However, it has been reported that also starvation-induced spores accumulate trehalose to even higher amounts than glycerol-induced spores (McBride & Zusman, 1989). Our data suggest that the trehalose accumulation is not only due to increased enzyme activity but also up-regulation of the gene for trehalose synthase.

To gain insight into patterns of gene expression during glycerol-induced development, the up-regulated genes were clustered based on their expression profile. Interestingly, this hierarchical clustering revealed two distinct regulation patterns suggesting two waves of gene expression. Distribution of known sporulation marker genes in the two generated heat maps (**Figure 2-4 b**) suggests that most genes essential for conversion into resistant, viable spores (such as *exo*, *fdgA*, *cbgA*, *Mxan_3026* and *Mxan_1101*) are enriched in Map 1 containing immediately up-regulated genes. Genes that are necessary for spore maturation (such as genes for spore coat proteins U, S and S1) are enriched in Map 2 together with later expressed genes. We cannot rule out that there are subsequent groups of genes expressed since data from later time points were excluded from the analysis. Our findings are supported by a proteomics approach using SDS-PAGE (Komano *et al.*, 1980) where distinct patterns of protein synthesis during glycerol-induced spore formation were observed, although sequence and function of the proteins were not determined. Quantitative measurements of DNA-, RNA- and protein synthesis during glycerol spore formation also identified a biphasic profile (Sadler & Dworkin, 1966). These results suggest that not only the starvation-induced developmental program requires tightly controlled gene expression cascades (Kroos, 2007), but also the core spore formation process itself is divided into early and later stages.

3.1.3 Genes involved in cell envelope related processes likely are important for spore formation

Spore formation in *M. xanthus* is very distinct from spore formation in Gram-positives. This is emphasized by the fact that *cbgA* is the only sporulation-related gene in *M. xanthus* that has been identified by sequence homology to a *Bacillus sp.* spore cortex protein. Approaches to identify *M. xanthus* spore formation genes by homology to genes of other Gram-negative spore formers are not successful since the sporulation process in Gram-negative bacteria is not understood.

The most obvious differences between *M. xanthus* spores and vegetative cells are found in the cell envelope. Shape, ultrastructure, and composition are very different which is emphasized by the recent finding that glycerol-induced spores do not contain significant amounts of peptidoglycan (Bui *et al.*, 2008). The spore envelope is largely responsible for the increased resistance properties since less resistant sporulation mutants often display defects in their spore envelopes (such as *fdgA*, *exo*, *cbgA*, *mSP A* and *C* mutants). Likewise, the results of our small-scale mutagenesis approach support this assumption.

We selected up-regulated genes from different functional categories for inactivation by insertion mutagenesis. Although this mutagenesis was not saturating, the surprising result was that the both mutants which displayed defects in glycerol-induced spore formation are putatively affected in envelope modifications.

Therefore, up-regulated hypothetical genes encoding for proteins that likely localize to the cell envelope appear to be good candidates to identify novel core sporulation genes in *M. xanthus*. Our transcriptional profiling data indicate that almost 25% of the cell envelope associated proteins were differentially regulated (**Figures 2-2** and **2-3**) which also suggests large changes in envelope associated proteins. However, the role of many of these proteins is unknown because their assignment to this particular category is often only due to a predicted lipid modification or alpha-helix fold (**Table A-15**). This means, from a functional point of view, these genes are of unknown function.

3.2 The *nfs* locus consists of hypothetical genes encoding for proteins involved in the core sporulation process

The identified *nfs* locus supports the conclusion that sporulation-specific expressed hypothetical genes that are predicted to localize to the cell envelope form a sufficiently defined group to search for novel core sporulation genes. Deletion of the *nfs* genes does not affect vegetative growth or fruiting body formation. However, the fruiting bodies fail to darken and the spores inside are less viable. Additionally, the mutant is not able to form refractile, resistant glycerol spores. This suggests that the *nfs* genes represent core sporulation genes.

The phenotype of the Δnfs strain during glycerol spore formation is intriguing. Upon glycerol-induction, cells shorten but seem unable to acquire refractivity or an optical dense spore envelope. Refractivity in phase contrast indicates spore maturation by desiccation suggesting that *nfs* mutants are not able to complete the process. Instead, the translucent ovoids convert back into rod-shaped cells. This re-elongation is accompanied by transient formation of malformed, spiral-like cells. Interestingly, mutants in *exo* likewise do not form glycerol- and starvation-induced spores, whereas fruiting body formation is not affected. Like in the Δnfs mutant, glycerol-induced *exo* cells shorten but do not form spores and convert back into rod-shaped cells (Licking *et al.*, 2000). Because of this similar phenotype, it is possible that *nfs* and *exo* are involved in the same cellular process.

exo resides in a locus consisting of nine genes likely involved in carbohydrate synthesis and trafficking (**Table A-15**). Glycerol spores do not contain peptidoglycan (Bui *et al.*, 2008). Assuming that *exo* and Δnfs cells degrade their cell walls too but fail to modify the cell envelope correctly (for example by export and cross-linking of carbohydrates or deposition of coat proteins) this could explain formation of non-refractile, translucent and enlarged ovoids approximately six to eight hours after addition of glycerol when wild type spores gain refractivity.

By an unknown mechanism, the cells unable to finish spore formation convert back into rod-shaped cells which could suggest that there exists check points or sensing mechanisms that monitor progress of the spore formation and are able relieve cells from

this developmental pathway if they cannot pass through the next stage. This contrasts spore formation in *Bacillus*, where the process cannot be interrupted after certain stages have been passed. In *M. xanthus* however, also starvation-induced sporulation can be interrupted at any stage by repletion of nutrients. The Δnfs mutant forms non-refractile spores also inside fruiting bodies suggesting that cells that undergo starvation-induced development are likewise unable to finish the sporulation process. In fruiting bodies however, the spheres do not convert back into rods. This may happen because the fruiting body environment provides additional signals preventing cells from re-elongating or it could be due to the lack of nutrients. The latter could explain the strongly reduced viability of starvation-induced spores. If the cells cannot finish spore formation but stay in a non-dormant state or try to grow out without nutrients, they could use up their energy sources and finally die.

3.3 Nfs-expression during starvation-induced development is C-signal dependent and controlled by FruA

The Δnfs and *exo* mutants display similar phenotypes both in starvation- and glycerol-induced sporulation. To test whether the gene products function in the same process during spore formation, we first examined whether both mutants share the same dependency on developmental marker genes during starvation-induced sporulation. To be able to quantify the activity of the *nfs* promoter in various developmental mutant backgrounds, we fused the putative *nfs* promoter region to *mcherry* as a reporter.

The quantitative fluorescence measurements of developing cultures suggest that *nfs* expression during starvation-induced development is entirely dependent on *csgA* and therefore on C-signaling. The *csgA*-mutant is blocked early in development; it does not aggregate or sporulate. In the *dev* mutant background however, *nfs* promoter-driven gene expression was detected, but less than in the wild type. The *dev*-mutant does not form mature fruiting bodies and the number of spores is strongly reduced (Boysen *et al.*, 2002). This result suggests that *nfs*-expression depends partially on the *dev* locus. In the *exo* mutant background, wild type levels of *nfs* expression were detected suggesting that *nfs* regulation is independent of *exo*.

fruA is also a non-developing mutant. The FruA-protein is a transcription factor with a central role during starvation-induced development. The protein is thought to be phosphorylated and this modified form is proposed to allow the developmental program to proceed by differential control of gene expression (**Figure 1-6**) (Ellehaug *et al.*, 1998). Unexpectedly, we saw a strong and early increase of *nfs* promoter-driven fluorescence in the *fruA* mutant compared to wild type. This result was confirmed by Nfs immunoblot on time-course samples from an independent *fruA* mutant strain (data not shown). Interestingly, unpublished results (X. Shi & L. Sogaard-Andersen) suggest that *exo* is likewise transcribed in the non-developing *fruA* mutant. A possible explanation is that *nfs* as well as *exo*-expression during starvation-induced development is controlled by FruA and that FruA is involved in repression of these genes during early development (**Figure 3-1**).

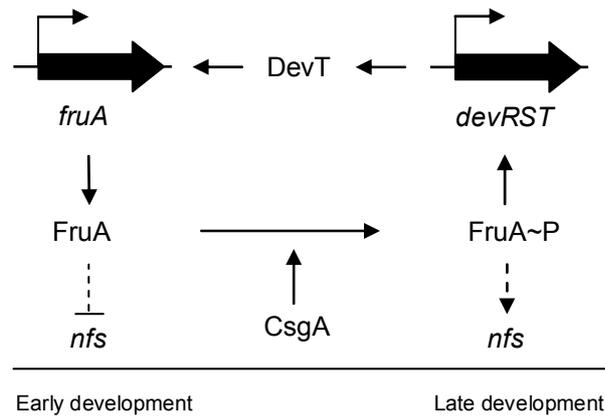

Figure 3-1 Schematic model of *nfs* expression control. During early stages of development, unphosphorylated FruA represses *nfs* expression directly or indirectly. CsgA triggers FruA phosphorylation. Phosphorylated FruA induces *devT* expression and DevT stimulates *fruA*-expression. High levels of FruA~P relieve repression of late developmental genes such as *nfs*.

However, fluorescence measurements cannot provide direct evidence for accumulation of the Nfs-proteins in spore forming cells. Accumulation of the signal does not necessarily reflect increasing promoter activity since the Mcherry protein may have different stability properties than the Nfs-proteins. An important next step to investigate whether *nfs* and *exo* participate in the same process is to generate a Δnfs *exo* double mutant. Analysis of glycerol- and starvation- induced Δnfs , *exo* and Δnfs *exo* mutants as well as wild type by electron microscopy should reveal if there are similar defects or missing layers in the spheres.

3.3.1 The Nfs proteins likely participate in a cell envelope-associated functional complex

The observation that the single *nfs* in-frame deletion mutants display phenotypes similar to deletion of the entire locus suggests that the proteins function together. This assumption is supported by the reduced stability of the Nfs proteins in single gene deletion backgrounds.

The Nfs proteins are detectable by immunoblot 30 minutes after addition of glycerol. At this time, gene expression levels are already at maximum. After two hours, all six detectable proteins accumulate to highest levels but only NfsA and B are stably detected until twelve hours. Analysis of protein stabilities in the single gene deletion backgrounds have shown that stability of NfsD to H strongly depends on presence of NfsA, B and C. However, if NfsD to H are missing, NfsA, B, to C levels are only reduced. These results could mean that the Nfs proteins do not form one large tight complex but two interacting complexes consisting of NfsA, B, C and of NfsD to H. Alternatively, NfsA, B and C may constitute a specific part of the complex that localizes to a different compartment (such as the outer membrane) and is therefore more stable (i.e. protected from degradation) than the remaining Nfs proteins. This possibility is supported by CELLO localization predictions that suggest that the first three proteins localize to the outer membrane.

NfsA and H likely are beta-barrel fold containing proteins. Beta-barrel structures are a characteristic motif of outer membrane proteins. NfsD contains a predicted N-terminal transmembrane domain. Therefore, the protein probably localizes to the cytoplasmic membrane. For NfsG, psiBlastp alignments suggest that this protein is related to ABC-transporters or ATP binding proteins. Additionally, Phobius prediction suggests that the N-terminal part is cytoplasm-exposed (containing the FHA-domain) and the C-terminal part localizes to the periplasm. Both parts are separated by a hydrophobic segment. Therefore, the protein likely also localizes to the cytoplasmic membrane. NfsE contains a lipid attachment site. Based on the amino acid sequence (+2 D sorting rule, (Seydel *et al.*, 1999)), the protein likely localizes to the outer membrane. For NfsB, C and F no clear prediction for a membrane anchoring structure or modification exists. Detection of NfsB and C in the cell envelope fraction by immunoblot suggests that those proteins are in a complex with the membrane anchored Nfs-proteins. NfsB and C share the protein stability pattern with NfsA suggesting that those proteins are in an outer membrane associated complex. NfsF contains a predicted signal peptide but no structural motif. The protein was not detectable by immunoblot. Therefore, localization and putative interaction partners for the small protein are not certain.

Based on the available data, we propose the following organization of the Nfs-proteins in the cell envelope (**Figure 3-2**):

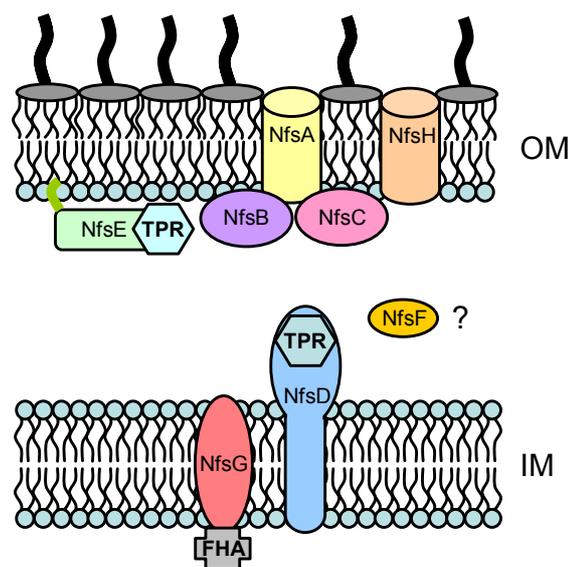

Figure 3-2 Schematic model of subcellular Nfs protein localization. OM: Outer membrane, IM: Inner membrane.

The predicted association of NfsA, B, C, E and H with the outer membrane and NfsD and G with the inner membrane needs to be confirmed by immunoblot of each separated membrane. To prove the assumed complex formation of the Nfs-Proteins, cross-linking and co-immunoprecipitation can be applied. To determine the stoichiometry of the proteins in the putative complex, quantitative immunoblot or *in vitro* complex formation analyses need to be performed. *In vivo* interaction can indirectly be shown by co-localization (fluorescent labelling or immunofluorescence) and directly by FRET-experiments with fluorescent markers that are known to function in the cell envelope such as Mcherry or Gfp and its derivatives when exported by the Tat-system.

During starvation-induced development, only two Nfs proteins were detected due to the strongly decreasing protein content of a developing culture and the fact that only a small proportion of cells convert into spores. To confirm that the Nfs proteins accumulate similarly during starvation-induced sporulation, the immunoblot analyses have to be carried out on samples of the spore-forming subpopulation. Recently, the experimental conditions for separation of cell subpopulations have been determined (B. Lee & P. Higgs, unpublished). This approach should improve immunoblot results since it specifically enriches *nfs* expressing cells (only spore forming cells activate the *nfs* promoter as shown by fluorescence microscopy).

The reason for the inability to delete *nfsC* is intriguing. The protein contains a predicted domain of unknown function and may be related to prenyltransferases. It is unlikely that the protein is essential since the entire locus can be deleted without apparent influence on vegetative growth. The inability to even recombine in either the up- or downstream region of the gene may suggest that this particular genomic region is difficult to access by DNA-recombination approaches.

3.3.2 The Nfs-proteins are probably involved in cell envelope modifications

Position specific iterative Blastp searches suggested that the Nfs-proteins could be related to glycosyl- and glucosamintransferases. One interesting result of the array analysis supporting the psiBlastp results is that the four mutants *fdgA*, $\Omega 7536$ (*exo*), *Mxan_1101* and *Mxan_3026* defective in glycerol- and, in case of *exo* and *fdgA* also starvation-induced spore formation, contain mutations in genes belonging to the GO-functional sub-category 'Biosynthesis and degradation of surface polysaccharides and lipopolysaccharides'. Five of the ten up-regulated genes in this category are annotated as glycosyltransferases or N-acetylglucosamine epimerases which matches the psiBlastp results for NfsC, D and E. Glycosyltransferases form a large family of enzymes that catalyze the transfer of sugars or aminosugars to various substrates including proteins, lipids and peptidoglycan (Lairson *et al.*, 2008) (Mohammadi *et al.*, 2007). Therefore, putative functions of the Nfs proteins could be glycosylation of spore-specific proteins or their target could be the cell wall, i.e. they could be involved in coordinated cell wall modification or degradation during spore formation. If the peptidoglycan sacculus is not properly disassembled during spore formation but, for example, stays present either completely or as patches of cell envelope associated murein, spore formation could be perturbed. Interestingly, in *E. coli*, aberrant branched and spiral-like cell shapes have been reported to be associated with patches of inert peptidoglycan (de Pedro *et al.*, 2003) and inhibition of penicillin binding proteins (Varma & Young, 2004). To analyze if the Δnfs mutant is defective in these putative functions, both protein glycosylation and peptidoglycan synthesis of the Δnfs mutant were investigated.

Most studies about protein glycosylation have been carried out in eukaryotic systems. Here, glycosylation is one of the most important post-translational protein modifications. However, there exist an increasing number of glycosylated bacterial proteins. Interestingly, in bacteria surface exposed proteins are frequently glycosylated such as pilins, adhesins, S-layer proteins (Ku *et al.*, 2009, Voisin *et al.*, 2005, Steiner *et al.*, 2007, Messner *et al.*, 2008) as well as cortex and exosporium proteins of *Bacillus*

spores. Apparently, glycosylation of surface proteins utilizes different modules of the biosynthesis routes of lipopolysaccharide O-antigens. The sugar moieties are transferred from an activated precursor either as mono- or as oligosaccharide to the target protein by glycosyltransferases. In *E. coli*, this reaction has been shown to take place in the periplasm. Interestingly, in *S. parasanguinis*, a cluster of seven genes has recently been identified involved in biogenesis and glycosylation of a conserved surface glycoprotein and interaction of glycosyltransferases has also been shown (Bu *et al.*, 2008) coinciding with the assumed interaction of the Nfs proteins. In *M. xanthus*, at least one surface glycoprotein (VGP) has been described (Glufka & Maeba, 1991) suggesting that *M. xanthus* possesses the ability to modify exported proteins by glycosylation. Therefore, we reasoned that one possible function of the Nfs-proteins could be to glycosylate and facilitate export of spore coat associated target proteins.

Since all detectable Nfs-proteins migrate approximately at their calculated molecular mass in SDS-PA-gels, they are probably not extensively modified themselves by glycosylation. A hypothetical target protein is therefore likely not part of the *nfs* locus. However, clear differences in protein glycosylation patterns between wild type and Δnfs were not detectable with the applied staining method. Techniques with better resolution such as chromatography and mass spectrometry could provide clearer results and samples of cells that have been induced for more than four hours should also be included because spore coat proteins may be synthesized and exported very late. Additionally, separated spore coats or outer membrane fractions of induced cells could be used for these analyses to enrich for the putative target protein(s).

Another cell envelope structure that is extensively modified both during spore formation and germination is the murein sacculus. In particular, upon spore germination, the peptidoglycan cell wall needs to be re-synthesized. To check if there are differences in cell wall synthesis during vegetative growth and germination in wild type and the Δnfs mutant, staining of nascent peptidoglycan with Fluorescein labeled Vancomycin (VanFL) was applied. As expected, differences during vegetative growth were not observed consistent with the assumption that the Nfs proteins function specifically during spore formation. However, preparation of samples from outgrowing cells proved difficult because cells in this stage were very fragile. Therefore, modified fixing and staining methods should be applied. For instance, cells could be fixed on poly-L-lysine coated slides or treated on micropore filters to avoid mechanical forces. Nevertheless, some germinating cells displayed bright fluorescence signals at the tips of outgrowing spheres or patches of labeled peptidoglycan as expected suggesting that an optimized procedure could help to understand how outgrowing spores synthesize peptidoglycan *de novo* and organize it into a rod-shaped sacculus.

An additional possibility is that the Nfs proteins could be directly involved in synthesis of the carbohydrate containing spore envelope. Biogenesis and assembly of outer membrane components such as lipid A as well as the O-antigen carbohydrate chains and exopolysaccharides is accomplished by export from the inner leaflet of the cytoplasmic membrane, transport through the periplasm and insertion in the outer membrane. This process can involve a type I-like secretion system (Bos *et al.*, 2007). Type I secretion systems consist of an inner-membrane ABC-transporter, an outer membrane protein and a 'membrane fusion protein' which connects the inner- and outer membrane

components (Gentshev *et al.*, 2002, Gentshev *et al.*, 2004) (Faridmoayer *et al.*, 2007). The *M. xanthus* spore carbohydrate translocation and exporting machinery could be similarly organized and the cell envelope associated Nfs proteins may be part of this machinery. NfsG is a good candidate for an inner membrane transporter since it probably localizes to the cytoplasmic membrane, is related to ABC-transporters and possesses a cytoplasmic FHA domain that could mediate interaction with a precursor-delivering protein or nucleotide-activated sugar moiety. NfsA and H could represent the outer membrane part of the functional entity and the other Nfs proteins could mediate delivery of the carbohydrates through the periplasmic space.

It is still unknown whether the carbohydrates in the spore coat are cross-linked. If they are, the cross-linking enzymes need to localize in the cell envelope. A possible task of the Nfs proteins could therefore also be to crosslink the subunits of the spore coat. If the carbohydrates are synthesized and exported but not cross-linked, the subunits (i.e. glucose and galactosamine) may be found in the medium.

Additional evidence about the function of the Nfs proteins could also be obtained from an envelope analysis of the ovoids formed by the Δnfs and *exo* mutants during glycerol induction and the spore-like entities formed inside fruiting bodies by electron microscopy. Furthermore, differences in the carbohydrate contents between Δnfs and *exo* as well as wild type spores could help to reveal what the *M. xanthus* spore envelope consists of. Additionally, the phenotype of an *nfs* constitutively or overexpressing mutant could provide insights in the mechanism of how the Nfs proteins function. Therefore, the strong *pilA* promoter could be cloned in front of the *nfs*-locus. Providing this mutant is viable, an aberrant envelope of vegetative cells and cell shape defects are possible.

3.4 The fate of the rod-shape determining protein MreB depends on the sporulation pathway and plays a crucial role in spore germination

A key organizer of bacterial cell shape and cell wall synthesis is the actin-like protein MreB. *In vivo*, MreB is a cytoplasmic protein but it aggregates into membrane attached twisted, dynamic, spiral-like filaments that traverse the long-axis of the cell. Depletion of MreB in rod-shaped Gram-negative bacteria leads to defects in cell wall synthesis, formation of spheres, and then cell lysis whereas repletion reconstitutes rod-like cell shape (Figge *et al.*, 2004). MreB filaments are thought to indirectly position the cell wall synthesizing proteins (penicillin binding proteins – PPBs) and autolysins both during vegetative cell elongation and cell division (Divakaruni *et al.*, 2007, den Blaauwen *et al.*, 2008).

During spore formation, *M. xanthus* converts from rod-shaped cells into spherical spores and, during germination, back into rods suggesting extensive remodeling of the cytoskeleton as precondition for cell wall transformation. As mentioned above, it has been shown that *M. xanthus*' glycerol spores do not contain peptidoglycan (Bui *et al.*, 2008). Therefore, during sporulation, the peptidoglycan of vegetative cells must be degraded. Since the bacterial cell wall is essential to counteract the turgor pressure and

to prevent cell lysis in a hypoosmotic environment, the peptidoglycan has to be replaced by another structure simultaneously accompanied by cell shape change. This process needs to be tightly controlled to avoid leakage and cell lysis. During germination however, this exchange has to be reverted. In this case, the protective carbohydrate and protein coat must be degraded and replaced by a rod-shaped, evenly-growing murein sacculus in a similar tightly controlled manner.

To analyze the role of MreB during the shape change conversions *in vivo*, we first tried to generate a strain containing a fluorescently labeled version of MreB. We could only obtain mutants containing the N-terminal label suggesting that the C-terminal labeled version is lethal. However, specific fluorescence signals could not be observed. Similar results were reported from E. M. F. Mauriello & D. Zusman (personal communication). A possible reason for these results is that the modified version of MreB is not as efficiently assembled into filaments as the native form. Therefore, we tried to overexpress the labeled version by expressing it under control of the strong *pilA* promoter. Although overexpression of the labeled *mreB* led to detectable fluorescence signals, it also caused severe cell shape defects. In other organisms, where the MreB spirals could successfully be visualized (such as *B. subtilis* and *E. coli*), the modified version of the gene was brought under control of an inducible promoter. Therefore, a similar way to fine-tune expression of *gfp-mreB* in *M. xanthus* could solve this issue. For that reason, an appropriate tightly-inducible promoter needs to be identified.

Our simultaneous second approach was to generate antibodies to MreB. After affinity purification of the antisera, antibodies of sufficient sensitivity and specificity could be obtained. Recent results suggest that MreB-spirals can successfully be detected by immunofluorescence in fixed vegetative *M. xanthus* cells (E. Cserti & P. Higgs, unpublished data). Localization and patterns of MreB during spore formation and germination should be analyzed.

Interestingly, our immunoblot analyses show that glycerol- and starvation-induced spores differ in their content of MreB. In glycerol spores, MreB is detectable throughout the whole spore formation process in similar amounts. During starvation-induced sporulation however, MreB decreases after 30 hours coinciding with the onset of spore formation suggesting controlled proteolysis of MreB. Since both types of spores are spherical, two different types of cytoskeleton re-arrangements need to be evoked. First, during starvation-induced development, MreB is likely degraded. Absence of MreB may allow formation of spherical cells (it is not yet known if starvation-induced spores contain peptidoglycan). Second, in the case of glycerol-induced spore formation, MreB is still present, but cells round up. MreB filaments could either be disassembled or the filaments are maintained but adapt their pitch to accommodate a spherical cell shape. In the latter case, the connection between MreB and cell wall synthesis likely becomes interrupted. This possibility is attractive since glycerol spores do not contain peptidoglycan. In glycerol spores, MreB still localizes to the cell envelope as shown by immunoblot on fractionated cell lysates. A similar observation was made in *Vibrio parahaemolyticus* when the cells enter the viable but nonculturable state and convert into small spheres (Chiu *et al.*, 2008). Therefore, it will be interesting to determine if the MreB in glycerol spores is still organized in a helical structure (as, for example in

spherical *E. coli* cells with inhibited PBP2, (Mohammadi *et al.*, 2007)) or in a diffuse, membrane attached pattern.

Addition of A22 to rod-shaped *M. xanthus* cells in CTT medium leads to formation of spheres and cell lysis suggesting that *M. xanthus* MreB is prone to A22 treatment. Interestingly, glycerol spores are prevented from outgrowth in the presence of A22. Starvation-induced spores brought back into rich medium synthesize MreB *de novo* but do also not elongate. Instead, both types of spores stay spherical and slowly lose refractivity suggesting that re-organization of the MreB cytoskeleton is an essential first step during germination. This assumption needs to be confirmed by MreB immunofluorescence on germinating spores. Simultaneous labeling of nascent peptidoglycan could show how MreB is involved in *de novo* synthesis of a rod-shaped cell wall.

3.5 Conclusion

The research in this thesis focused on the process of spore formation in the Gram-negative bacterium *M. xanthus*, i.e. on conversion of entire rod-shaped cells into spherical, resistant spores. As model for this process we applied glycerol-induced spore formation. Our transcriptome profiling data suggest that glycerol induction specifically activates the core sporulation genes and represents an appropriate system to analyze spore formation and cell shape change in *M. xanthus*.

We propose that synthesis and export of carbohydrates and assembly of a carbohydrate containing spore envelope is an important process to replace the peptidoglycan by a spore specific envelope structure and to generate resistant spores from vegetative cells. Considering the unusual spiral-like cell morphology of the Δnfs strain during elongation, we speculate that this mutant degrades its peptidoglycan like the wild type but fails to replace it by a carbohydrate and protein coat. During conversion from enlarged ovoids back into rods, the re-establishing cytoskeleton governs peptidoglycan-synthesis without the protecting spore coat and the spiral-like morphology becomes visible.

The currently discussed models of bacterial cell wall growth require an existing peptidoglycan matrix. New cell wall material is incorporated by controlled hydrolysis of glycosidic and peptide bonds and insertion of precursors at specific sites leading to a continuously growing sacculus and preventing lysis (Vollmer *et al.*, 2008, Vollmer & Holtje, 2004). *M. xanthus* glycerol-induced spores however, do not contain a preexisting peptidoglycan matrix which means that emergence of a rod-shaped sacculus during germination is not explained by the current models of bacterial cell wall synthesis. Upon germination, the right cell shape and diameter has to be determined by another mechanism and translated into the emerging cell wall. Analysis of the Nfs proteins in combination with the rod-shape determining protein MreB both during spore formation and germination can therefore be utilized to study fundamental mechanisms of cell shape determination and cell wall morphogenesis in Gram-negative bacteria.

4 MATERIALS AND METHODS

4.1 Reagents, technical equipment and software

Common reagents, enzymes and antibiotics used in this study are listed in **Table 4-1** together with their suppliers. Specific chemicals are described in the text. Technical equipment and its manufacturers are listed in **Table 4-2** and specific software applied for data analysis is listed in **Table 4-3**.

Table 4-1 Sources of reagents, enzymes, antibiotics and kits

Reagent	Vendor
Media components, Agar-Agar	Roth (Karlsruhe) Merck (Darmstadt) Difco (Heidelberg)
Pure chemicals	Roth (Karlsruhe) Merck (Darmstadt)
SDS-PAGE size standards	MBI Fermentas (St. Leon-Rot)

4.2 Media

Culture media for *E. coli* were prepared as described (Sambrook *et al.*, 1989). All strains were cultivated aerobically. Antibiotics and X-Gal were added if selection for antibiotics resistance or blue-white screening was intended.

Table 4-4 Growth media for *E. coli*

Medium	Composition
Luria-Bertani (LB)	1% (w/v) tryptone, 0.5% (w/v) yeast extract, 1% (w/v) NaCl
Salt free LB	1% (w/v) tryptone, 0.5% (w/v) yeast extract
LB agar plates	LB-Medium, 1% (w/v) Agar-Agar

Table 4-5 Additives

Additive	Final concentration	Dissolved in
Ampicillin-Sodiumsalt	100 µg/ml	H ₂ O
Chloramphenicol	50 µg/ml	99.9% Ethanol
Gentamycinsulfate	10 µg/ml	H ₂ O
Kanamycinsulfate	100 µg/ml	H ₂ O
Oxytetracyclin-Dihydrate	10 µg/ml	0,1M HCl
X-Gal	40 µg/ml	DMF

M. xanthus strains were grown in 1% CTT, in CTTYE or CYE medium.

Table 4-6 Growth media for *M. xanthus*

Medium	Composition
1% CTT	1% (w/v) Bacto™ Casitone, 10 mM Tris-Cl, pH 8.0, 1 mM potassiumphosphate buffer, pH 7.6, 8 mM MgSO ₄
1% CTT agar plates	1% CTT-medium, 1.5% (w/v) Agar
CTT soft agar	1 % CTT-medium, 0.75% (w/v) agar
CTTYE	1% CTT-Medium, 0.2% (w/v) yeast extract
Casitone yeast extract (CYE) (Campos & Zusman, 1975)	1% (w/v) Bacto™ Casitone, 0.5% (w/v) yeast extract, 10 mM MOPS pH 7.6, 8 mM MgSO ₄
CYE agar plates	CYE medium, 1.5% (w/v) agar

For *M. xanthus* developmental assays, nutrient limitation or strict starvation media were prepared as follows:

Table 4-7 Media for *M. xanthus* developmental assays

Medium	Composition
Clone fruiting (CF) agar plates (Hagen <i>et al.</i> , 1978) Prepared at least 24h before use	10 mM Tris-Cl, pH 8.0, 1 mM potassiumphosphate buffer, pH 7.6, 8 mM MgSO ₄ , Added after autoclaving: 0.015% (v/v) CTT medium, 0.02% (w/v) (NH ₄) ₂ SO ₄ , 0.1% (w/v) Na-pyruvate, 0.2% (w/v) Na-citrate, 1.5% (w/v) agar
TPM agar plates (Kuner & Kaiser, 1982) Prepared at least 24h before use	10 mM Tris-Cl, pH 7.6, 1 mM potassium phosphate buffer, pH 7.6, 8 mM MgSO ₄ , 1.5% (w/v) agar
MMC-buffer for submerged culture	10 mM MOPS, pH 7.0, 4 mM MgSO ₄ , 2 mM CaCl ₂

4.3.2 Media and cultivation of bacteria

Media and solutions were autoclaved for 20 minutes at 121°C and 1 bar over pressure. Heat sensitive liquids as antibiotic- or carbohydrate-containing solutions were filtered using 0.22 or 0.45 µm pore size filters (Millipore, Schwalbach) and added after media have cooled to 60°C. Other equipment (such as glass ware, metal tools and ceramics) was sterilized at 180°C for three hours.

M. xanthus was cultivated aerobically at 32°C on 1% CTT agar in the dark. *M. xanthus* liquid cultures were inoculated by dispersion of single colonies by pipetting in an 1.5 ml Eppendorf tube containing 1 ml liquid medium. After dispersion, particles were pelleted briefly and the supernatant was transferred in an Erlenmeyer flask containing growth medium. Liquid cultures were grown on horizontal shakers at 240 rpm. Optical densities of *M. xanthus* liquid cultures were monitored at 550 nm (OD₅₅₀) using 1 cm path length.

E. coli was incubated aerobically on Luria-Bertani (LB-) agar at 37°C. *E. coli* liquid cultures were inoculated directly from single colonies into liquid medium and cultivated on horizontal shakers at 37°C and 240 rpm. The optical density was determined as above.

4.3.3 Storage of transformed *M. xanthus* and *E. coli* strains

M. xanthus and *E. coli* cultures on solid media were stored up to four weeks at 18 or 4°C, respectively. For long term storage, 10 ml cultures of *M. xanthus* were harvested at OD₅₅₀ = 0.8 by centrifugation and resuspended in 1 ml medium. *E. coli* strains were not concentrated but supplemented with 10 M glycerol (2 M final concentration) directly before shock freezing in liquid nitrogen and stored at -70°C.

4.3.4 Cultivation of *M. xanthus* for development

For starvation induced development, *M. xanthus* strains were grown to an OD₅₅₀ of 0.5 - 0.8 and harvested by centrifugation at 4.620 x g for 10 min at rt. The cell pellet was rinsed with MMC starvation buffer, centrifuged again for 5 min and resuspended in MMC buffer to a calculated OD₅₅₀ of 7.0. Development was assayed on CF (Hagen *et al.*, 1978) and TPM agar plates (Kuner & Kaiser, 1982) by applying 10 µl drops of cell suspension on the agar surface. After drying, the cultures were incubated at 32°C in the dark. For development in submerged culture, the cell suspension was diluted 1:8 with MMC buffer and 400 µl were pipetted in each well of a 24-well microtiter plate. For development in large (145 mm diameter) petri dishes, 40 ml cell suspension was added per dish. Aggregation and fruiting body formation was monitored with a Leica MZ8 stereo microscope (Leica, Herrbrugg) at 10- and 40-fold magnification. Images were taken after 24 h, 48 h, 72 h and 120 h.

4.3.5 Total protein isolation

For protein isolation, liquid cultures were transferred into centrifuge tubes and kept on ice. Developing submerged cultures were harvested from Petri dishes and transferred into centrifuge tubes. The dishes were rinsed once with MMC buffer and the buffer combined with the sample. After centrifugation (4.620 x g, 10 min, 4°C) supernatants were removed and the pellets were stored at -20°C or processed directly on ice.

Cell pellets were resuspended in 1/100 vol. ice cold buffer (10 mM HEPES, 150 mM NaCl) supplemented with mammalian protease inhibitor cocktail (Sigma, Taufkirchen). Up to 600 µl sample were transferred into 2 ml screw cap tubes filled with 0.6 g 0.1 mm zirconia/silica beads (BioSpec, Bartlesville, OK). Cells were mechanically disintegrated using a FastPrep[®]-24 tissue and cell homogenizer (MP Biomedicals, Illkirch, France) six times for 45 s each at 6.5 m/s speed. The supernatant was recovered, the bead matrix washed once with the same volume of buffer and the supernatants combined.

For protein recovery from samples of equal initial cell numbers, supernatants were not removed after cell lysis. Instead, equal volumes of 2 x LSB (0.125 M Tris-HCl pH 6.8, 20% (v/v) glycerol, 4% (v/v) SDS, 10% (v/v) betamercaptoethanol, 0.02% (w/v) coomassie G-250) were directly added to the tubes containing lysed cells with bead matrix and heated to 99°C for 10 min.

4.3.6 Cell fractionation

Cell lysates were separated into their soluble and insoluble fractions by ultracentrifugation at 100,000 x g and 4°C for 30 min (Sorvall Ultra Pro 80). The soluble fraction containing supernatant was recovered and the insoluble fraction containing pellet was washed twice and resuspended in an equal volume of 2 x LSB.

4.3.7 Determination of protein concentrations

Protein concentrations were determined after Bradford (Bradford, 1976) using the Bio-Rad protein assay kit (Bio-Rad, München) according to the instructions of the

manufacturer. Standard curves were obtained using dilutions of protein standard (bovine serum albumin). All sample protein concentrations were determined in triplicate with 50, 20 and 5 μ l of a 1:10 dilution in 1 ml reaction volume. Absorbance was measured at 595 nm with an Ultrospec 2100 pro spectrophotometer (Amersham). Protein concentrations were calculated based on the slope value of the standard curve.

4.3.8 *M. xanthus* sporulation efficiency and spore viability

Sporulation efficiency of developing and glycerol induced cultures was determined by spore counting. After harvesting, cells were resuspended in 1 ml sterile water and spores were isolated from vegetative and non-resistant cells by heating (2 h at 50°C) followed by sonication at 30 kHz and 30 W output for 30 s in ice water. 10 μ l of the treated samples were applied to a Thoma cell counting chamber (Hawksley, Lancing, UK). Spore numbers were calculated as per cent of wt.

Spore viability was determined by germination assays. 10-fold serial dilutions of heat- and sonication-treated cells were plated in CTT soft agar and incubated for two weeks. Colonies were counted after 5, 10 and 14 days. Colony numbers were calculated as per cent of wt.

4.4 Molecular biological methods

4.4.1 Oligonucleotides and plasmids

Oligonucleotides used as primers to amplify gDNA and cDNA templates are listed in the Appendix, **Table A-1**. Plasmids and expression vectors generated are listed in **Table 4-8**.

4.4.2 Construction of plasmids

Purified *M. xanthus* genomic DNA was used as template to amplify chromosomal regions for cloning.

pFM20 - 28 (in-frame deletion of *nfs* genes): Those plasmids are pBJ114 derivatives and used for markerless in-frame deletion of specific genomic regions as described in **Section 4.4.4**. The corresponding *E. coli* clones were selected on LB plates containing kanamycin, X-Gal and IPTG. Isolated plasmids were sequenced to confirm the inserts were error-free and subsequently introduced into *M. xanthus* DK1622 to generate strains PH1200 - 1208.

pFM30 - 44 (insertion mutagenesis by plasmid integration): Approximately 500 bp internal fragments of the genes to be disrupted were PCR-amplified, purified and directly cloned into pCR[®]2.1 TOPO (Invitrogen). The corresponding *E. coli* colonies were selected on LB plates containing kanamycin, X-Gal and IPTG. Isolated plasmids were sequenced to confirm correctness of the insert and subsequently introduced into *M. xanthus* DK1622 to generate strains PH1231 - 1244 by homologous recombination (**Figure 4-1**).

pFM50: This plasmid was constructed for heterologous over expression of *M. xanthus mreB* in *E. coli*. The gene was amplified and cloned into pET32a⁺ (Novagen) to generate pFM50. The corresponding *E. coli* clones were selected on LB agar containing ampicillin. The plasmid was sequenced to confirm the sequence was error-free and in-frame with tags and transferred into several expression strains.

pAL4 and its derivatives pFM16, pFM17, pFM18: These plasmids were used to fuse the putative *nfs* promoter region to *mcherry* as reporter. First, the *nfs* promoter region and *mcherry* were amplified with primers that allow for subsequent fusion of both fragments by overlap extension PCR and cloning into pFM10 (Mx8 *attP*, Km^R). The inserts were sequenced and introduced into *M. xanthus* strains.

PFM3 - 9 (fluorescent labelling of MreB): The *M. xanthus mreB*-gene was amplified by PCR and 5'-fused to *gfp* and *egfp* separated by a 16 and 12 amino acids spacer maintaining the reading frame. This fragment was cloned behind the putative *mreB* promoter region as well as behind the *pilA* promoter (for overexpression) and introduced into *M. xanthus* DK1622.

4.4.3 Generation of *M. xanthus* insertion mutants

Genes were disrupted by site directed insertion of a plasmid via homologous recombination and selection for antibiotics resistance as shown in **Figure 4-1**. The vector used cannot replicate in *M. xanthus*. Therefore, only insertion events give rise to resistant colonies. Insertion mutants were selected on kanamycin and verified by PCR using oligonucleotides specific for the pCR[®]2.1 TOPO plasmid and a neighboring region up- or downstream of the target gene. At least two independent colonies were used for further studies.

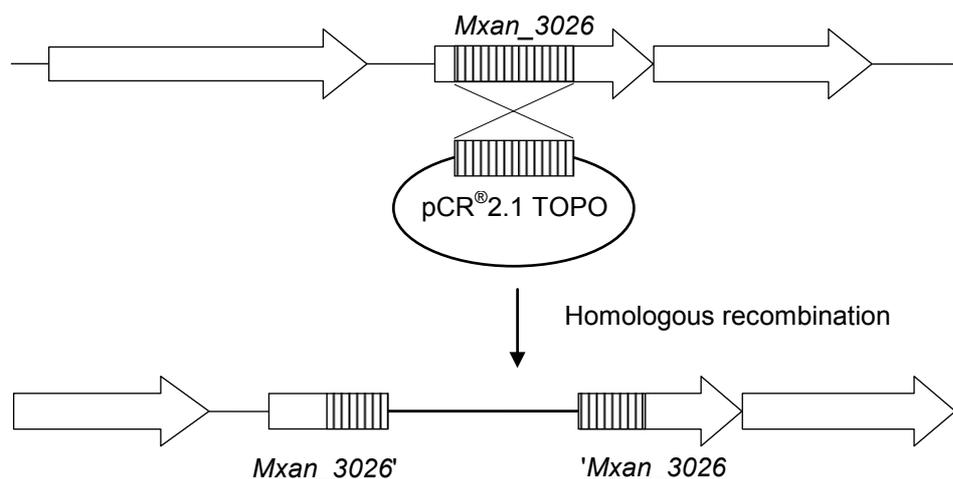

Figure 4-1 Generation of insertion mutants. A central part of the target gene of approximately 500 bp length was amplified by PCR. The purified PCR product was cloned into the pCR[®]2.1 TOPO plasmid. The plasmid was propagated in *E. coli* and after re-isolation electroporated into *M. xanthus* where homologous recombination leads to disruption of the target gene.

4.4.4 Construction of *M. xanthus* in-frame deletion mutants

In-frame deletions of specific genomic regions were generated applying the technique of (Ueki *et al.*, 1996) and (Sun & Shi, 2001). Therefore, approximately 500 bp fragments directly up- and downstream of the target region were amplified by PCR. The inner primers were designed to possess compatible ends which allow fusing the 500 bp fragments in a second PCR to a 1 kB contig maintaining the reading frame. This contig was cloned into pBJ114 and sequenced. Plasmids with error-free inserts were electroporated into *M. xanthus*.

pBJ114 cannot replicate in *M. xanthus* but provides for kanamycin resistance. Thus, growing *M. xanthus* colonies possess a plasmid insertion likely up- or downstream of the target region. Insertions were mapped by PCR and both, up- and downstream insertion mutants were isolated, if possible.

pBJ114 also contains the counterselectable marker *galK* (*E. coli* galactokinase gene) which converts galactose into its phosphorylated form. Since *M. xanthus* cannot metabolize galactose phosphate, the compound accumulates to toxic levels when cells are grown on galactose containing media. Thus, only cells that have undergone a second recombination to excise the plasmid are viable. However, only 50% of the growing mutants will have lost the vector and the genomic region, the remaining 50% will have lost only the vector and restore the original genomic situation providing the target gene is not essential (**Figure 4-2**).

The insertion mutants were grown in CTT medium to an optical density of 0.5. 200 μ l of this culture were added to 3 ml CTT soft agar and plated on CTT agar containing 1% (w/v) galactose. Emerging colonies were transferred to CTT medium containing galactose or kanamycin. Colonies growing on galactose but not on kanamycin were used to verify deletions by PCR.

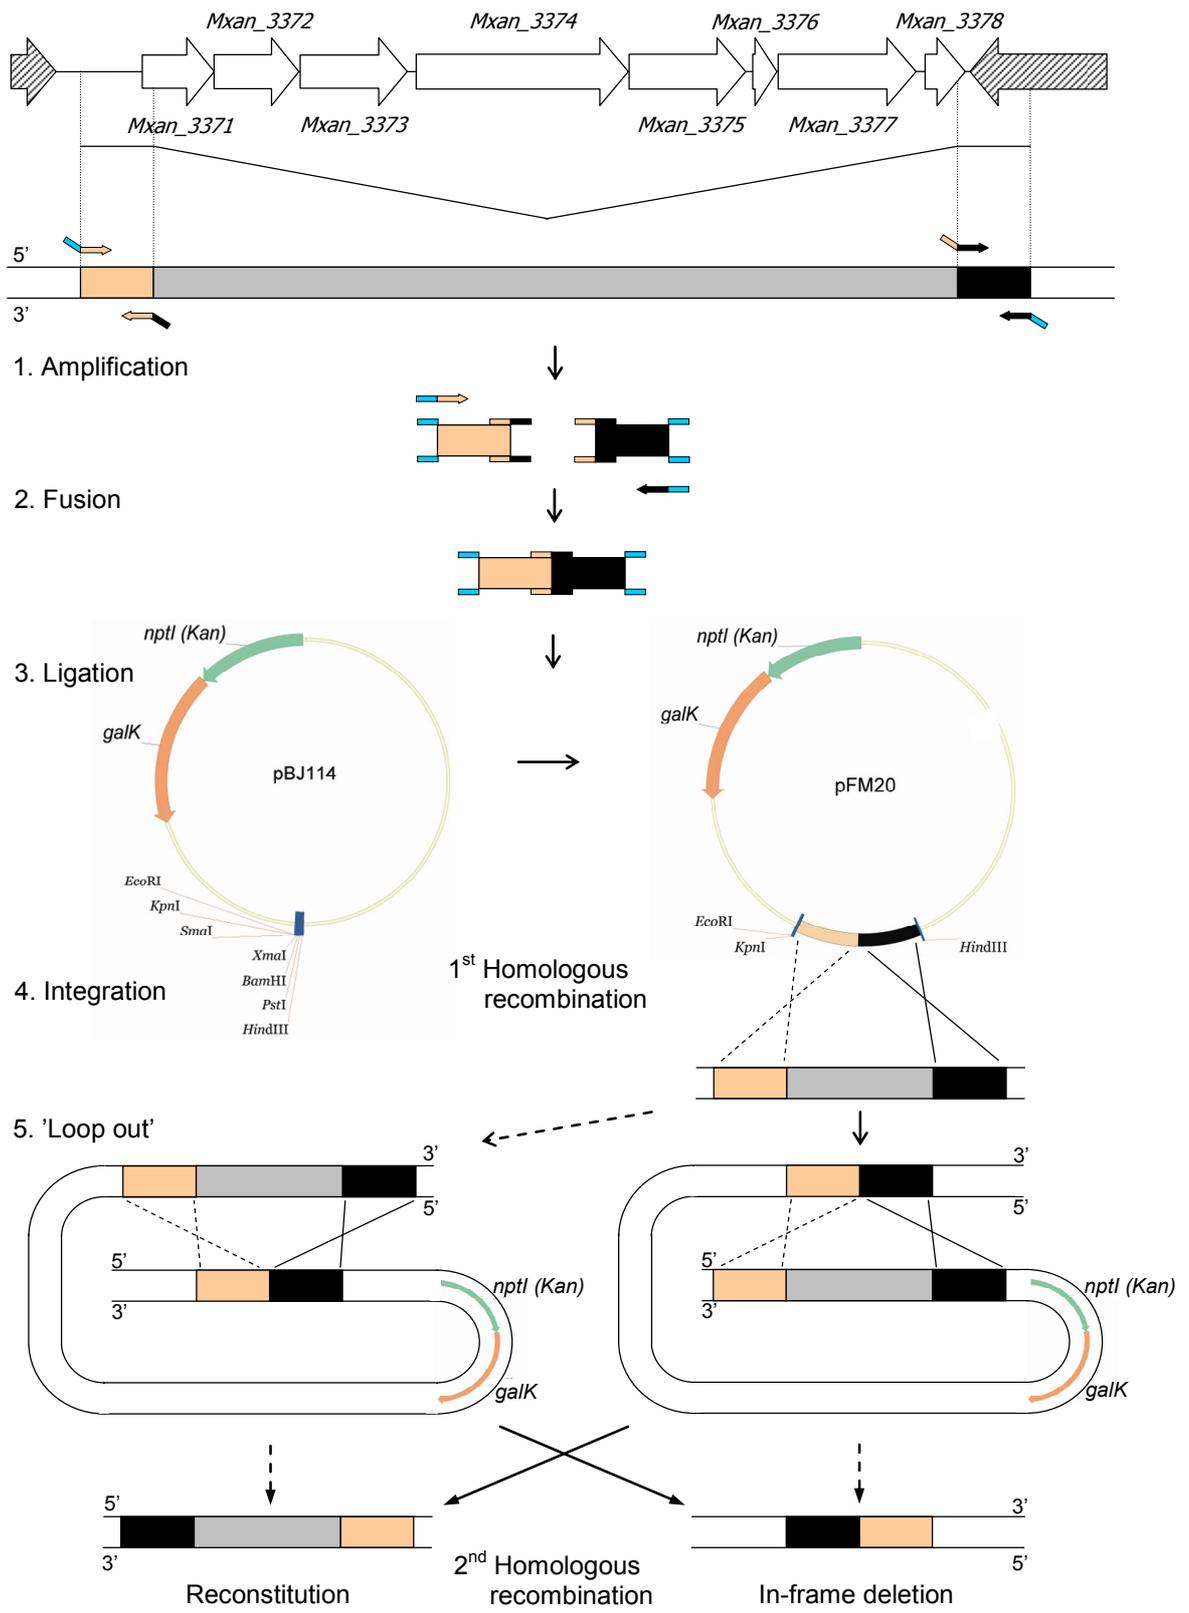

Figure 4-2 Scheme of markerless in-frame deletion mutagenesis. The first homologous recombination leads to plasmid integration up- or downstream of the genomic region to be deleted. The second recombination event eliminates only the vector (reconstitution) or the vector with the target region (in-frame deletion).

4.4.5 DNA preparation from *E. coli* and *M. xanthus*

Plasmid-DNA from *E. coli* was isolated using the QIAprep Spin Miniprep-Kit (Qiagen). *M. xanthus* genomic DNA was prepared using the Master Pure DNA purification kit (Epicentre) according to the instructions of the manufacturer. Concentration and purity was determined with the Nanodrop ND-1000 spectrophotometer (Nanodrop, Wilmington).

Quick DNA preparations to verify the presence of insertions by PCR were done by boiling cell samples for 10 min in 50 μ l sterilized deionized water followed by cooling on ice and brief sedimentation of cell debris.

4.4.6 Polymerase chain reaction (PCR)

Amplification of specific DNA-fragments was carried out in 25 or 50 μ l reaction volumes in FailSafe™ PCR PreMix J (Epicentre) with *Taq* DNA polymerase or with Platinum® *Pfx* DNA polymerase (Invitrogen) if sequence fidelity was required.

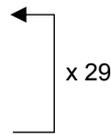

Table 4-9 PCR reaction mix (25 μ l)

Component	Volume	Final concentration
2 x FailSafe™ PCR PreMix J	12.5 μ l	1 x
10 μ M primer	1 μ l each	0.4 μ M
Genomic or plasmid DNA	1 μ l	10 pg - 200 ng
DNA Polymerase (2.5 U/ μ l)	0.5 μ l	0.05 units
Sterile water	9 μ l	-

A standard PCR reaction is shown (Table 4-10). The reaction conditions were modified based on predicted primer annealing temperatures, expected product sizes and DNA-polymerase.

Table 4-10 Standard PCR program

Step	Temperature	Time
Initial denaturation	95°C	3 min
Denaturation	95°C	30 s
Primer annealing	5 to 8°C below predicted melting temperature	15 s
Polymerization	72°C	1 min per kb
Final elongation	72°C	5 min
Hold	4°C	∞

PCR products were purified with the QIAquick® PCR Purification Kit (Qiagen) or the DNA clean and concentrator™ Kit (Zymo Research) or extracted from agarose gels.

4.4.7 Agarose gel electrophoresis

Nucleic acid fragments were separated by size with agarose gel electrophoresis at 9 Volt per cm in TAE buffer. Ethidiumbromide was added to agarose in a final concentration of 0.01% (v/v). 6 x sample loading buffer (30% (v/v) glycerol, 50 mM EDTA, 10 mM Tris-HCl pH 7.5, 0.44 μ M bromphenolblue, 0.28 μ M xylencyanol, 8.8 μ M orange G) was combined with samples to 1 x final concentration. After electrophoresis, agarose gels were imaged using a 2UV-Transilluminator (UVP-Bio-Doc-IT-System, UniEquip) at 365 nm wavelength and documented with an electronic P93E thermoprinter (Mitsubishi). DNA fragments were isolated from agarose gels by cutting out and purification with the QIAquick[®] Gel Extraction Kit.

4.4.8 Restriction und ligation of DNA fragments

Restriction of DNA was carried out by incubation of 5 - 10 μ g DNA with restriction endonucleases for 2 h according to specific requirements for the enzyme. Restricted DNA was purified with the QIAquick[®] PCR Purification Kit (Qiagen) or the DNA clean and concentrator[™] Kit (Zymo Research). Fragments of specific size were isolated by agarose gel extraction.

Ligation reactions were performed with T4 DNA ligase. DNA fragments were ligated into vectors applying a 2.5-fold molar excess of insert-DNA. Usually, 20 fmol insert and 50 fmol vector DNA were ligated for 2 h at room temperature (complementary ends) or with PEG added at 18°C over night (blunt ends) followed by heat inactivation of the enzyme at 65°C for 15 min.

4.4.9 Preparation of electrocompetent *E. coli* cells

Over night cultures of *E. coli* strains were used to inoculate 200 ml LB-medium. Cells were grown at 37°C shaking at 240 rpm to an OD₅₅₀ of 0.6 and harvested by centrifugation at 5,000 x g for 20 min, 4°C. The cell pellet was resuspended in 200 ml ice cold sterile 10% (v/v) glycerol and centrifuged again. The washing steps were repeated with 100 ml, 50 ml and 10 ml volumes. Finally, the cell pellet was resuspended in 0.4 ml 10% sterile glycerol and 50 μ l aliquots were shock frozen in liquid nitrogen and stored at -70°C for later use.

4.4.10 Preparation of chemically competent *E. coli* cells

Over night cultures of *E. coli* strains were grown as above in 20 ml LB-medium. At OD₅₅₀ = 0.6 the culture was immediately cooled on ice and harvested by centrifugation at 5,000 x g for 10 min at 4°C. The cell pellet was resuspended in 2 ml ice cold sterile TSS pH 6.5 (1% (w/v) tryptone 0.5% (w/v) yeast extract, 1% (w/v) NaCl, 10% (v/v) PEG (3350 or 8000 g/mol) 5% (v/v) DMSO, 50 mM MgCl₂ (Chung *et al.*, 1989)). 100 μ l aliquots were shock frozen in liquid nitrogen and stored at -70°C.

4.4.11 Transformation of electrocompetent *E. coli* cells

2 - 5 μ l heat inactivated ligation reaction were added to 50 μ l electrocompetent *E. coli* cells on ice. The suspension was transferred into an electroporation cuvette and pulsed with 1.8 kV, 25 μ F and 200 Ω . 500 μ l LB medium were added, the suspension transferred into a sterile plastic tube and incubated for 1 h at 37°C shaking at 240 rpm. 5, 20 and 200 μ l aliquots were then plated on LB agar containing appropriate antibiotics. The plates were incubated at 37°C over night, colonies transferred onto fresh agar plates and screened for the presence of the plasmid by PCR.

4.4.12 Transformation of chemically competent *E. coli* cells

100 μ l aliquots of chemically competent *E. coli* cells were transformed on ice by adding 1 - 5 μ l plasmid DNA, gently mixing followed by incubation on ice for 30 min. Cells were then heat shocked at 42°C for 2 min. After addition of 0.5 ml LB, cells were incubated at 37°C shaking at 240 rpm for 1 h. 20, 50 and 200 μ l were plated on LB agar containing appropriate antibiotics and incubated over night at 37°C. Colonies were transferred on fresh LB agar and screened for the presence of the plasmid by PCR.

4.4.13 Transformation of *M. xanthus* cells

M. xanthus strains were grown in 100 ml CYE medium to an OD₅₅₀ of 0.4 and harvested by centrifugation at 4.620 x g for 10 min at rt. The cell pellet was resuspended in 50 ml sterile deionized water and centrifuged as above. This washing step was repeated three times. The pellet was then resuspended in 150 μ l sterile water and the suspension divided into 50 μ l aliquots and either shock frozen in liquid nitrogen or used directly for electroporation.

3 - 8 μ l plasmid DNA (corresponding to calculated 1 μ g DNA) were transferred to the suspension of electrocompetent cells. The suspension was transferred into a 0.1 cm electro-poration cuvette and pulsed with 650 V, 25 μ F and 400 Ω . 1 ml CYE medium was added immediately, the culture transferred into a fresh plastic tube and incubated at 32°C and 240 rpm in the dark for 5 h. Then, 50, 200 and 500 μ l aliquots were added to 3 ml top agar, vortexed and used to overlay a CYE agar plate containing appropriate antibiotics. The plates were incubated at 32°C for 5 to 14 days and colonies transferred to fresh CTT agar plates.

Site specific recombination was verified by PCR. To verify plasmid integration at the *M. xanthus attB* phage attachment site, three PCR reactions with primers specific for the genomic *attB* locus and the plasmid specific *attP* site were performed (Magrini *et al.*, 1999). The length of PCR products was determined by agarose gel electrophoresis.

4.4.14 DNA sequencing

DNA sequencing was performed applying the chain termination method after Sanger. Sequencing reactions were set up using the Big Dye[®] Terminator[™] Cycle Sequencing Kit (Applied Biosystems, Darmstadt) according to the instructions of the manufacturer in a 20 μ l reaction volume and incubated as shown in **Table 4-11**. Reaction products were

purified either by DNA precipitation or with the BigDye[®] XTerminator[™] Purification Kit (Applied Biosystems).

For precipitation, 10 μ l 125 mM EDTA, 9 μ l 3 M sodium acetate (pH 4,6), 80 μ l HPLC-H₂O and 400 μ l 96% ethanol were added to the reaction and incubated for 30 min at rt. DNA precipitates were pelleted by centrifugation at 15,000 x g for 30 min at 20 °C. The supernatant was removed and the pellet washed twice with freshly prepared 70% ethanol followed by 5 min centrifugation at 15,000 x g each. Finally, the ethanol was removed and the pellet air dried. For sequencing, the pellet was dissolved in 20 μ l formamide. DNA sequences were analysed with the Vector NTI software suite 9.

Table 4-11 Incubation times and temperatures for DNA sequencing reactions

Step	Temperature	Time	
Initial denaturation	96°C	1 min	
Denaturation	96°C	10 s	← x 29
Primer annealing and elongation	60°C	4 min	
Hold	10°C	∞	

4.4.15 Quantitative real time polymerase chain reaction

Quantitative real time polymerase chain reaction was applied to determine changes of single gene expression levels during time course experiments. For this purpose, target gene specific oligonucleotides were designed to amplify fragments of approximately 80 -100 bp length. Oligonucleotide pairs with equal predicted melting temperatures of approximately 61°C were preferred. To avoid formation of primer homo- and hetero-dimers, the derived sequences were checked using netprimer (<http://www.premierbiosoft.com/netprimer/netprlaunch/netprlaunch.html>). Specificity of the oligonucleotides was tested on genomic DNA under standard PCR conditions (**Table 4-10**). One single PCR product of the expected size indicated specificity of each primer pair under these conditions.

Efficiency of each primer pair was determined using a 10-fold dilution series of genomic DNA (10 ng, 1 ng, 100 pg and 10 pg) as template. The reactions were performed as duplicates in 26 μ l volumes with a 7300 Real Time PCR System using the SYBR[®] Green PCR Master Mix (Applied Biosystems).

Table 4-12 Real time PCR reaction mix (26 μ l)

Component	Volume	Final concentration
SYBR [®] Green PCR Master Mix	13 μ l	1 x
5 μ M oligonucleotide	1 μ l each	0.2 μ M
Template (cDNA or gDNA)	1 μ l	0,4 ng – 0,4 pg
Sterile water	10 μ l	-

Table 4-13 Real time PCR program

Step	Temperature	Time	
Initial denaturation	95°C	10 min	
Denaturation	95°C	15 s	
Primer annealing and elongation	60°C	1 min	← x 40
Denaturation	95°C	15 s	
Recording of dissociation curve	60°C	30 s	
	95°C	15 s	
Hold	10°C	∞	

Primer efficiencies were calculated by plotting values for the threshold cycle (C_t) over the logarithm of the relative template copy number. The slope value m of the obtained regression curve was used to determine the primer efficiency E as

$$E = 10^{-\frac{1}{m}}$$

Only primer pairs with efficiencies near two were considered for further experiments.

cDNA was generated from DnaseI treated, purified total RNA extracts (**Section 4.8**). Priming was performed by adding 2 μ l random hexamers (pd(N)₆, 100 ng/ μ l, Amersham), 1 μ g total RNA (<10 μ l), 1 μ l dNTP mix (10 mM, Fermentas) and Rnase-free H₂O to a final volume of 13 μ l. The reagents were incubated at 70°C for 5 min to denature secondary structures and then chilled on ice.

Reverse transcription was initiated by adding 4 μ l 5 x RT buffer (Invitrogen), 1 μ l SUPERase Rnase inhibitor (20 U/ μ l, Ambion), 1 μ l SuperScript III reverse transcriptase (200 U/ μ l, Invitrogen) and 1 μ l 0.1 M DTT. The reaction was incubated at 25°C for 5 min, 55°C for 50 min and 70°C for 15 min. For each time point, a control reaction without added reverse transcriptase was carried to check for absence of contaminating gDNA.

The optimal cDNA concentration for each target gene was determined by running real time PCR reactions on a series of cDNA dilutions. cDNA concentrations that resulted in exceeding the C_t after 25-30 cycles were chosen. Additionally, the melting curves were screened to exclude primer dimer formation and to confirm overlap of the dissociation curves.

All real time PCR reactions with the determined optimal primer pairs, cDNA concentrations and controls were performed in duplicate. Control reactions contained no cDNA (no reverse transcriptase) and H₂O (no template) as negative controls and gDNA as positive control.

Data were analyzed by first averaging the C_t values of the duplicate samples. Then, the ΔC_t values were determined by subtracting the C_t value for each time point from the C_t value of the $t = 0$ h sample. Thus, the ΔC_t value of $t = 0$ h was zero and the ΔC_t values

for the single time points reflect the relative change in template copy numbers at each time point.

The relative amount of transcript T_{rel} was quantified using the correlation

$$T_{rel} = E^{\Delta C_t}.$$

4.5 Biochemical methods

4.5.1 Heterologous overexpression and purification of *M. xanthus* MreB in *E. coli*

M. xanthus mreB was expressed in three *E. coli* strains. Various conditions were tested to optimize the yield in soluble protein.

The gene was cloned into plasmid pET32a⁺ (Novagen) (designated pFM50) which is optimized for inducible protein over expression in *E. coli* and provides fusion tags to facilitate protein purification. The gene for MreB was amplified and cloned in-frame with both a N- and C-terminal his-tag. Sequencing confirmed that the inserted gene was error-free and the vector transferred into *E. coli* BL21λDE3 (with and without pLysS) and *E. coli* GJ1158.

Over night cultures were used to inoculate 600 ml LB medium supplemented with either ampicillin (100 μg ml⁻¹ for BL21λDE3 and GJ1158) or ampicillin and chloramphenicol (100 μg ml⁻¹ for BL21λDE3 pLysS) and incubated at 37°C shaking at 240 rpm. At an OD₅₅₀ = 0.6, 1 ml culture was harvested by centrifugation and resuspended in 2 x LSB. For the remaining culture, *mreB* expression was induced by incubation with 1 mM IPTG (for BL21λDE3 and BL21λDE3 pLysS) or 0.3 M NaCl (for GJ1158) and the culture was grown for 2 h at 37°C. Alternatively, induction was carried out with 0.5 mM IPTG and growth at 18°C over night or with heat shock at 42°C followed by incubation with 0.5 mM IPTG at 37°C for 2 h or using the overnight autoinduction system (Novagen) solutions according to manufacture's instructions. After incubation, the cells were harvested by centrifugation at 4°C. All cultures were grown aerobically and aerated by constant shaking. Protein production was monitored by SDS-PAGE.

4.5.2 Protein purification

Overexpressed *mreB* was purified by affinity chromatography. Cell pellets were resuspended in binding buffer (10 mM HEPES, 150 mM NaCl, 10 mM imidazole, pH 7.4) and passed three times through a French Pressure Cell Press at 103.4 MPa. Inclusion bodies were separated from the lysate by centrifugation at 600 x g for 30 min at 4°C. The supernatant was filtered through a 0.45 μm pore size filter and further purified by affinity chromatography using Ni-NTA-Agarose resin (Qiagen). The resin was washed and equilibrated with binding buffer, the supernatant added to the resin and incubated for 1 h at 4°C slowly rotating to allow binding of the tagged protein. The suspension was then transferred to a Poly Prep chromatography column (Bio-Rad) and the chromatography was started by collecting the flow through followed by washing the

column with 10 volumes of binding buffer. Elution was carried out with 5 column volumes of elution buffer with increasing imidazole concentrations (50 -500 mM). Samples of each fraction were combined with equal volumes of 2 x LSB and loaded on a SDS-PA gel to visualize success of the purification. To remove imidazole, the samples were dialyzed against 10 mM HEPES, 150 mM NaCl, pH 7.4.

Fractions enriched in the target protein were further purified by anion exchange chromatography using the Äkta™ Unicorn™ 5.0 HPLC system (Amersham biosciences). For this purpose, samples were dialyzed against 50 mM Tris pH 7.6 and loaded on a MonoQ column. Elution was performed applying a gradient of 0 – 50 % of a 2 M NaCl solution in 50 mM Tris pH 7.6. Fractions were screened for their protein content spectrophotometrically and by loading samples on a SDS-PA gel.

4.5.3 Harvesting of inclusion bodies

E. coli BL21λDE3 pLysS pFM50 was grown at 37°C and induced in 1 mM IPTG for 2 h. Cells were harvested by centrifugation (20 min, 10.000 x g, 4°C). The cell pellet was resuspended in lysis buffer (10 mM HEPES, 150 mM NaCl, pH 7.4) supplemented with 5 µg/ml DnaseI, 2.5 mM MgCl₂ and 0.5 mg/ml lysozyme and incubated on ice for 30 min. The suspension was then homogenized using a syringe and passed 3 times through a French Pressure Press Cell. Inclusion bodies were separated from the cell lysates by centrifugation (600 x g, 30 min, 4°C). The pellet was washed three times with lysis buffer supplemented with increasing concentrations of triton X-100 (0, 1 and 2 %) to remove membrane associated proteins. Aliquots were taken each time to monitor the separation process by SDS-PAGE. After washing, the amount of protein was estimated as follows: The specific A₂₂₀ absorption of the protein was computed based on the amino acid composition. The pellet was then solubilized in 2 x LSB without bromphenol blue and the absorbance of a 100-fold dilution was measured photometrically. The protein concentration was calculated based on the absorption value.

4.5.4 SDS Polyacrylamide Gel Electrophoresis (SDS-PAGE)

SDS-PAGE (Laemmli, 1970, Schägger & von Jagow, 1987) was performed to monitor heterologous protein expression, to separate and to purify proteins under denaturing conditions. To denature proteins, samples were combined with equal volumes of 2 x Laemmli sample buffer (LSB; 0.125 M Tris-HCl pH 6.8, 20 % (v/v) glycerol, 4 % (w/v) SDS, 10 % (v/v) β-mercaptoethanol, 0.02 % (w/v) bromphenol blue) and heated at 96°C for 5 min prior to loading the gel. PageRuler™ prestained protein ladder (Fermentas) was used to estimate the molecular weight of proteins. Electrophoresis was performed in Bio-Rad electrophoresis chambers (Bio-Rad, München) at 120 – 150 V in 1 x Tris-glycine-SDS running buffer (25 mM Tris, 190 mM glycine, 0,1% (w/v) SDS). The electrophoresis was stopped when the bromphenol blue dye front passed the bottom of the resolving gel. Proteins were visualized by soaking the gel in staining solution (25% (v/v) methanol, 10% (v/v) acetic acid, 0.25% (w/v) Coomassie brilliant blue R250) for 30 min and in destaining solution (28% (v/v) methanol, 10% (v/v) acetic acid) until protein bands became clearly visible.

Table 4-14 Composition of a 13% resolving and a 5 % stacking gel

Component	Resolving gel (10 ml)		Stacking gel (5 ml)	
	Volume	Final concentration	Volume	Final concentration
water	3 ml	-	2.9 ml	-
1.5 M Tris-HCl (pH 8.8)	2.5 ml	375 mM	-	-
10% (w/v) SDS	0.1 ml	0.1%	0.1 ml	0.1%
0.5 M Tris-HCl (pH 6.8)	-	-	1.25 ml	125 mM
30% acrylamide/ bisacrylamide	4.3 ml	12.9%	0.825 ml	4.95%
TEMED	6 μ l	0.06%	3.75 μ l	0.75%
10% (w/v) APS	80 μ l	0.08%	50 μ l	0.1%

4.6 Immunoblot analysis

4.6.1 MreB antibody generation

Purified MreB inclusion bodies from *E. coli* cell lysates were run on a preparative SDS gel in a Protean[®] II XI Cell (Biorad). 200 μ g protein were loaded per lane. The gel was run at 4°C for 15 h at 11 mA in a TE62 tank transfer unit (Amersham). After the run, the gel was stained with autoclaved Coomassie in water for 30 min and then destained. The protein bands were cut out with a sterile scalpel and sent to Eurogentec (Seraing, Belgium) to immunize rabbits for antibody production.

4.6.2 Nfs antibody generation

Antibodies for Nfs-protein detection were generated by Eurogentec (Seraing) as peptide antibodies based on epitope prediction. The peptide sequences and their localization in each protein sequence are provided in the Appendix section (Table 5-14).

4.6.3 Affinity purification of MreB antibodies

The generated antisera displayed unspecific binding properties and needed to be affinity purified. Therefore, an adapted version of a protocol from Michael Koelle lab (Yale University) was applied: For purification of 2 ml serum, approximately 1 mg of the inclusion body fraction (containing the antigen MreB) was loaded on a SDS-PA gel and blotted on a PVDV membrane by electrophoretic tank transfer under standard conditions. The membrane was stained with Ponceau S in ddH₂O to visualize the protein and to mark its position on the membrane. Then, membrane and proteins were destained in ddH₂O, the MreB containing part of the membrane cut out and soaked in ddH₂O to remove remaining stain. Weakly bound protein was removed by soaking the membrane in acidic glycine buffer (100 mM glycine, pH to 2.5 with HCl) for 5 min. The membrane was washed and neutralized by soaking twice in TBS buffer (500 mM NaCl, 20 mM Tris pH 7.4, 0.05% (v/v) tween-20) for 2 min each and blocked in TBS-B

(3% (w/v) bovine serum albumin fraction V in TBS buffer) for 1 h with gentle rocking at rt. After blocking, the membrane was washed twice in TBS for 5 min each. Two ml serum were added to 8 ml TBS and incubated with the membrane for at 4°C over night slowly rolling to bind the antibodies. The membrane was recovered and soaked twice in TBS for 5 min. Bound antibodies were eluted by adding 1 ml of acidic glycine buffer (Harlow & Lane, 1988) and incubation at room temperature for 10 min with occasional vortexing. The antibody containing eluate was combined with 1 M Tris pH 8.0 leading to an antibody solution of pH 7.0. The elution step was repeated and the eluates unified. Purified antisera were stored at 4°C with 5 mM sodium azide and 1 mg ml⁻¹ bovine serum albumin to prevent degradation.

4.6.4 Immunoblot analysis

M. xanthus cells were harvested from submerged cultures, glycerol induced cultures or CTT broth cultures as described above, pelleted at 4°C and frozen at -20°C or processed directly on ice. The pellets were resuspended in 1 ml ice cold MMC buffer supplemented with mammalian protease inhibitor cocktail (Sigma) and total protein was released by disintegration with a FastPrep[®]-24 instrument (Section 4.3.5). Protein concentrations were determined as described (Section 4.3.7). Samples of 5 or 10 µg µl⁻¹ protein or of equal initial cell numbers were loaded on a SDS-PA gel. Depending on the calculated molecular weight of the target protein; 8, 11, 13 or 15% PA gels were prepared (Table 4-14). Proteins were blotted on methanol activated polyvinylidene fluoride (PVDF) membranes using a tank transfer system (Hoeffer) in transfer buffer (25 mM Tris, 192 mM glycine, 10% methanol, 0.1% SDS, pH 8.3). After blotting, the membranes were briefly soaked in methanol and air dried. For blocking, the membranes were re-activated in methanol, washed in ddH₂O and incubated in blocking buffer (PBS-T, 137 mM NaCl, 10 mM phosphate, 2.7 mM KCl, 5% (w/v) non-fat milk powder, 0.1% (v/v) tween-20, pH 7.4) for 1 h at rt or at 4°C over night gently shaking. Western blot analysis was performed using the primary antibody dilutions listed in Table 4-15. Secondary anti-rabbit IgG horseradish peroxidase (HRP) coupled antibodies (Pierce, Bonn) were added to a 1:20,000 dilution and incubated for 1 – 2 h at rt. After washing in PBS, chemiluminescence substrate (Pierce) was added and signals were detected by exposure to CL-Xposure Film (Pierce) or using the LAS-4000 luminescent image analyzer (Fuji).

Table 4-15 Dilutions of primary antibodies used for immunodetection.

4.7 Sources for bioinformatics analyses of nucleotide and amino acid sequences

M. xanthus DNA- and protein sequences were obtained online from TIGR (<http://www.tigr.org/cmr>) or NCBI (<http://www.ncbi.nlm.nih.gov/>) and analyzed using the Blastn (against nonredundant database), Blastp and psiBlastp algorithms from NCBI or the SMART algorithm from EMBL (<http://smart.embl-heidelberg.de/>). Predictions of subcellular protein localizations were carried out with SignalP (<http://www.cbs.dtu.dk/services/SignalP/>), the CELLO subcellular localization predictor (<http://cello.life.nctu.edu.tw/>), the subcellular localization prediction tool Psortb (<http://www.psort.org/psortb/>), the combined transmembrane topology and signal peptide predictor Phobius (<http://phobius.cbr.su.se/>) and the Subloc tool (<http://www.bioinfo.tsinghua.edu.cn/SubLoc/>). Prediction of lipoproteins and signal peptides was carried out with LipoP v. 1.0 (<http://www.cbs.dtu.dk/services/LipoP/>), Psortb and Phobius. To detect conserved domain structures, the TMHMM-Server (<http://www.cbs.dtu.dk/services/TMHMM-2.0/>) and the TMPred-Server (http://www.ch.embnet.org/software/TMPRED_form.html) were used. Protein 3-D structures were predicted using the protein fold recognition server Phyre (<http://www.sbg.bio.ic.ac.uk/~phyre/index.cgi>). The RED-TMBB-Server (<http://bioinformatics2.biol.uoa.gr/PRED-TMBB/index.jsp>) was used to predict beta barrel structures. Related protein sequences in prokaryotic genomes were detected by Blastp and psiBlastp from NCBI and FastBlast from the Virtual Institute for Microbial Stress and Survival (<http://www.microbesonline.org/>). Sequence alignments and vector maps were generated using the Vector NTI Suite 9 (InforMax, Oxford, UK).

4.8 Microarray experiments

4.8.1 Experimental setup

Microarray time course experiments were performed for global transcriptional profiling of glycerol induced spore formation. All experiments were done in three independent biological replicates. A schematic overview of the experimental setup is shown (Figure 4-3).

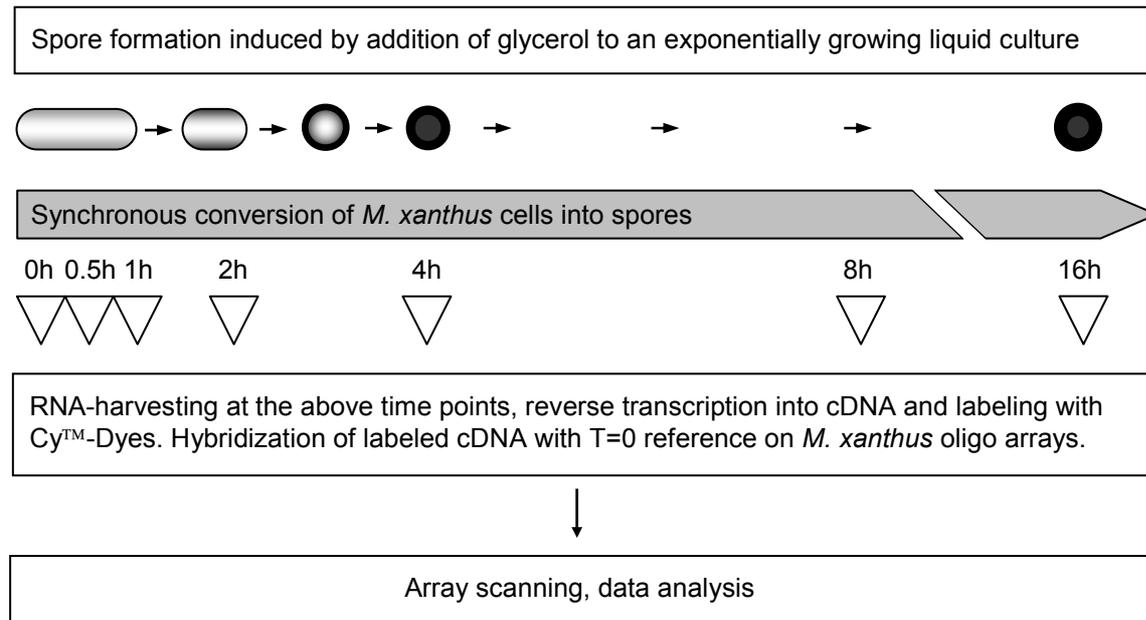

Figure 4-3 Schematic flow of a glycerol spore induction time course for micro array analysis.

A liquid culture of *M. xanthus* DK1622 was grown in CTT medium to an OD₅₅₀ of 0.5. Subsequently, half of the culture was added in 45 ml aliquots to 5 ml stop solution (5% saturated phenol pH < 7 in ethanol) and harvested by centrifugation at 4°C, snap frozen in liquid nitrogen and stored at -70°C until later use. The remaining culture was induced by addition of glycerol to a final concentration of 0.5 M. Samples were harvested at 0.5, 1, 2, 4, 8 and 16 h after induction and treated as the samples of uninduced cells. Spore formation was monitored microscopically.

4.8.2 Sample preparation, probe generation and hybridization

Total RNA was isolated from cell pellets using the hot phenol method (Overgaard *et al.*, 2006, Maniatis, 1982, Müller & Jakobsen, 2008). Cells were lysed by resuspending the frozen pellets in 2.5 ml ice cold solution 1 (0.3 M sucrose, 0.01 M NaAc, pH 4.5) and transfer into a 15 ml tube containing 2.5 ml hot (65°C) solution 2 (2% SDS, 0.01 M NaAc, pH 4.5). The suspension was mixed gently by inversion and immediately used for hot phenol extraction. For this purpose, 5 ml hot phenol (65°C) were added and the solution mixed gently by inversion followed by incubation at 65°C for 5 min. The

samples were chilled in liquid nitrogen for ~10 s, kept on ice and centrifuged at 4,500 x g for 5 min, 4°C. The aqueous layer was transferred to a fresh 15 ml tube containing 5 ml hot (65°C) phenol. The samples were mixed gently by inversion and incubated 5 min at 65°C, chilled in liquid nitrogen for ~10 s and centrifuged as above. For phenol/chloroform/isoamylalcohol extraction, the aqueous layer was transferred to a fresh 15 ml tube containing 5 ml phenol:chloroform:isoamylalcohol (25:24:1, pH 6.6), mixed gently by inversion and centrifuged as above. The samples were chloroform/isoamylalcohol extracted by transfer of the aqueous layer to a 15 ml tube containing 5 ml chloroform:isoamylalcohol (24:1), mixed gently by inversion and centrifuged at 4,500 x g for 5 min, 4°C. Nucleic acids were precipitated by transfer of the aqueous layer to a fresh 15 ml tube containing 400 µl 3M NaAc pH 4.5 and 9 ml 96% EtOH. The samples were inverted several times and incubated at -70°C for 30 min or at -20°C over night. Precipitates were pelleted by centrifugation at 4,500 x g for 30 min at 4°C. The pellets were washed twice with freshly prepared ice cold 70% ethanol, air dried and finally dissolved in 1 ml Rnase-free H₂O and stored at -70°C.

The RNA was further treated with DnaseI (Ambion) followed by Qiagen RNeasy[®] column purification according to manufacture's instructions to remove genomic DNA. Quality of isolated RNA was verified by agarose gel electrophoresis, absence of contaminating genomic DNA was confirmed by PCR.

Probes were prepared as follows: Random priming was carried out by addition of 10 µg random hexamers (pd(N)₆, Amersham) to 25 µg purified RNA in a final volume of 15.5 µl followed by incubation at 70°C for 10 min and chilling on ice. Reverse transcription was initiated by addition of 4.5 µl RNase free water, 3 µl 0.1 M dithiothreitol (DDT), 0.5 µl RNase inhibitor (20 U/µl, Ambion), 0.6 µl 50 x deoxynucleoside triphosphate mix (25 mM dATP, 25 mM dCTP, 25 mM dGTP, 10 mM dTTP, 15 mM aminoallyl-dUTP), 3 µl reverse transcriptase (50 U/µl, Stratagene) and incubation at 37°C for 10 min, 42°C for 1 h 40 min and 50°C for 10 min.

RNA was hydrolyzed by addition of 10 µl 1 N NaOH and 10 µl 0.5 M EDTA followed by incubation at 65°C for 15 min. Samples were purified with Zymo DNA clean and concentrator[™] spin columns (Zymo research) using freshly prepared phosphate wash buffer (5 mM KPO₄, 80% EtOH, pH 8.0) and elution buffer (4 mM KPO₄, pH 8.5). The samples were vacuum concentrated to ~1 µl and recovered in 7 µl 0.1 M fresh sodium bicarbonate pH 9.3. Then, NHS-ester dyes Cy[™]3 or Cy[™]5 (Amersham) were coupled to the amino groups of incorporated aminoallyl-dUTP. For this purpose, the lyophilized dyes were dissolved in 10 µl DMSO and 2 µl were added and samples were incubated for 2 h at room temperature in the dark. After purification with Zymo spin columns, labeling efficiency was determined photometrical and the labeled probes were either used directly for hybridization or stored at -20°C.

Prehybridization of arrays was performed by submerging the slides in a well dissolved, filtered (0.22 µm) solution of 5 x SSC buffer (pH 7.0), 0.1% SDS and 1% (w/v) BSA fraction V at 42°C for 2 hours. The slides were washed five times two minutes each in autoclaved ddH₂O at room temperature on a shaker, submerged in isopropanol for 2 min and finally dried by low speed centrifugation with a flat plate-holder adaptor for 10 min.

Probes were prepared for hybridization as follows: 22 μ l of hybridization buffer (50% formamide, 5 x SSC buffer, 0.1% SDS, 60 μ g salmon sperm DNA) were added to the labeled probes. Then, CyTM3- and CyTM5-labeled probes (representing reference and sample of one particular time point) were unified and heated at 95°C for three minutes.

After cooling to rt, the probes were applied to the prehybridized arrays, covered with a LifterSlipTM (Erie scientific) and mounted into a hybridization chamber. To avoid drying during incubation, 50 μ l of hybridization buffer were added to the chamber. Sealed hybridization chambers were incubated submerged in a water bath for 16 h at 42°C.

After hybridization, arrays were washed three times 10 min each in buffers providing increasing stringency conditions (buffer 1: 2 x SSC pH 7.0, 0.1% SDS, buffer 2: 0.1 x SSC, 0.1% SDS, buffer 3: 0.1 x SSC) in the dark and dried by low speed centrifugation. Thereafter, arrays were scanned with a GenePixTM4000B microarray scanner controlled by GenePixTM Pro 6.0 image analysis software (Axon instruments) at 532 nm (Cy3TM) and 632 nm (Cy5TM) wavelengths simultaneously.

4.8.3 Data analysis

Image analysis (block and spot finding, background detection) and data acquisition were performed with GenePixTM Pro 6.0 image analysis software. Each slide was checked manually for correct positioning of the grid and detection of each spot. Normalization and data analysis were carried out with Acuity 4.0 software package (Axon instruments) applying the following criteria: Normalization: Ratio based (mean ratio of medians = 1)

Substance name \neq EMPTY

Substance name \neq NULL

F532 Median – B532 \geq 100 OR F635 Median – B635 \geq 100 in at least one time point.

These pre-filtered datasets were analyzed with the Significance Analysis of Microarrays (SAM) software version 2.23 (Stanford University) to screen for significantly regulated genes. The three biological replicate time course experiments were analyzed separately as one class time courses. The signed area was considered for calculation. A false discovery rate (FDR) of 5% was applied to call a gene significantly regulated.

The sets of regulated genes were exported to Acuity and combined by averaging the values for each gene at each time point. Genes that display a log ratio < 1 or > 1 in at least one time point (corresponding to 2-fold up- or down regulation) and where data are present for all time points were called “genes regulated above threshold”.

The self-organizing map clustering algorithm of the Acuity software was applied to group significantly regulated genes based on their expression pattern. Yellow colors indicate upregulation, blue colors indicate downregulation.

The microarray data will be deposited in NCBI's Gene Expression Omnibus (<http://www.ncbi.nlm.nih.gov/projects/geo/>).

4.9 Plate reader experiments

Strains were grown in liquid to an $OD_{550} = 0.5$, harvested and developed in submerged culture in MMC buffer as described above in black 24-well glass bottom plates (Greiner Bio-One). At indicated time points, fluorescence signal intensity was measured at 615 nm wavelength in a plate reader (Tecan Infinite M200) controlled by i-control 1.4 software. Signals from cell-free, buffer containing wells were subtracted from signals of developing cultures to calculate absolute fluorescence intensities. Proper development was checked at each time point using a stereo microscope. All experiments were carried out in triplicate.

4.10 Labeling of nascent peptidoglycan with fluorescent vancomycin

Cells were grown in liquid. 1 ml samples were harvested by centrifugation (5000 x g, 10 min, 4°C) and fixed for 10 - 15 min by resuspension in 2.5 mM formaldehyde, 2.5% (w/v) paraformaldehyde, 30 mM NaH_2PO_4 pH 7.4. The fixed samples were split and one part was incubated with 3 μ g/ml fluorescein conjugated vancomycin (VanFL) for 10 min in the dark. Cells were sedimented by centrifugation (3000 x g, 5 min, rt) and the pellet rinsed with fixing solution. The supernatant was discarded; the cells were carefully resuspended and spotted on an agar pad (1% Agarose in A50 Puffer) for microscopy. Fluorescence signals were detected at 515 nm wave length.

4.11 Microscopic methods

For fluorescence microscopy, *M. xanthus* cells were spotted on Agar pads (1% (w/v) agarose in A50 starvation buffer (10 mM MOPS, pH 7.2, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 50 mM NaCl) covered with a cover slip and placed under the microscope. Phase contrast, DIC and fluorescence images were taken with 600- and 1000-fold magnification. Gfp and vancomycin specific signals were detected at 515 nm and Mcherry specific fluorescence signals were detected at 670 nm wavelength. The microscopes (**Table 4-2**) were controlled by Metamorph ver7.5 software. Images were taken with the camera types EM-CCD Cascade 1K (Photometrics, Tucson) or Leica DFC 350FX. Image processing was carried out with Metamorph ver7.5.

A APPENDIX

A.1 Oligonucleotides

All oligonucleotide primers used in this study were synthesized by MWG (Ebersberg) or Invitrogen (München). Underlined sequences indicate restriction sites used for cloning. Bolded sequences indicate complementary sequences that were used to fuse PCR products.

Table A-1 Primers used to generate in-frame deletion constructs and to screen in-frame deletion mutants. Primers del A and del 1 were used to generate the upstream fragment; primers del D and del 2 were used to generate the downstream fragment. Primers del A and del D were finally used to generate the fusion used for cloning. The chk primers were used to screen colonies for loss of the gene.

^apSL8 was provided by S. Leonardy & L. Sogaard-Andersen, Marburg. pSL8 is a pSWU30 derivative.

Table A-12 Primers used to construct pFM17 (pAL4 where Km^r is replaced by Tc^r). The oligonucleotides bind to flanking regions of the Tc^r-cassette of pSWU30. Since there was a interfering *Clal* site in the intended region, the Tc^r cassette was amplified in two parts and fused by PCR allowing for deletion of the *Clal* site. *Italicized* are mismatching positions that delete a *Clal* recognition site.

Name	Description	Sequence (5' → 3')
tet f1	To amplify the first fragment	AT GCT <u>AAG CTT</u> AAA TCA ATC TAA AGT ATA TAT GAT TAA ACT TGG

A.3 Micro array data analysis results

Table A-15 List of regulated genes with annotation (TIGR) and GO main role (TIGR) sorted by *Mxan_*-numbers. Criteria: Regulation is significant based on SAM analysis (FDR 5%); data present for all time points; threshold: log-ratio 532/632 nm ≥ 1 (= 2-fold up- or down-regulated) in at least one time point. Most genes mentioned in the text are bolded.

CURRICULUM VITAE

PERSONAL DATA

Name Frank-Dietrich Müller
Date/Place of birth 1973-01-09, Zwickau, Germany

EDUCATION

1991 – 1994 Studies of Management Sciences
University of Applied Sciences, Meissen, Germany
1994 Graduation: Diplom-Verwaltungswirt
1994 – 1995 Civilian service
1996 – 1999 Administration officer
1999 – 2001 Studies of Biology
University of Bayreuth, Germany
2001 Vordiplom
2001 – 2004 Studies of Biology, Majors: Microbiology, Genetics and Ecology
Friedrich-Schiller University Jena, Germany
2003 – 2004 Diploma thesis
Centre for Environmental Research Leipzig-Halle,
Dept. Environmental Microbiology, Germany
Topic: Microbial diversity of an acidic mining lake and changes of community composition caused by *in situ* remediation.
2004 Graduation: Diplom-Biologe
2005 – 2009 Philipps University and Max Planck Institute for Terrestrial Microbiology, Marburg, Germany
Dept. Ecophysiology
Supervisor: Dr. Penelope I. Higgs

ERKLÄRUNG

Ich erkläre, dass ich meine Dissertation

„Analyse des Sporulationsprozesses in *Myxococcus xanthus*“

selbstständig, ohne unerlaubte Hilfe angefertigt und mich dabei keiner anderen als der von mir ausdrücklich bezeichneten Quellen und Hilfen bedient habe. Die Dissertation wurde in der jetzigen oder einer ähnlichen Form noch keiner anderen Hochschule eingereicht und hat noch keinen sonstigen Prüfungszwecken gedient.
